CARDIOVASCULAR THERAPEUTICS: A COMPANION TO BRAUNWALD'S HEART DISEASE
ISBN-13: 978-1-4160-3358-5
ISBN-10: 1-4160-3358-0

Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment, and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on his or her experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assume any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

The Process of Regulatory Review for New Cardiovascular Devices

Foreword

As recently as four decades ago, the treatment options available for patients with cardiovascular disease were quite limited. The major therapeutic measures included bed rest and warfarin for acute myocardial infarction; nitroglycerin for angina pectoris; dietary sodium restriction, bed rest, digitalis, and mercurial or thiazide diuretics for heart failure; quinidine or procainamide for tachyarrhythmia; large, clumsy pacemakers for complete heart block; sodium restriction and sympathetic blocking agents for severe hypertension; and palliative surgery for a limited number of complex congenital cardiac malformations. Mild or even moderate hypertension was not treated, nor were effective agents available to lower serum cholesterol in patients with coronary artery disease and hypercholesterolemia. Percutaneous coronary revascularization, internal cardioverter-defibrillators, and modern pharmacotherapy of myocardial ischemia and fibrinolysis had not yet been developed. β-Adrenergic antagonists, angiotensin-converting enzyme inhibitors, and statins also were off in the future.

No aspect of medicine has undergone a more radical transformation in the past 40 years than has cardiovascular therapeutics, and the results have been truly spectacular. Overall mortality rates from heart disease have been declining steadily, and the age-adjusted mortality secondary to coronary artery disease, the most common cause of cardiovascular deaths, has been falling at almost 1% per year. Effective treatment—albeit not cure—of almost all forms of heart disease is now possible, allowing a majority of patients with cardiovascular disease to live longer lives of high quality.

Dr. Antman and his associate editors—Drs. de Lemos, Givertz, Josephson, Oparil, and Sacks—and a constellation of superb contributing authors should be congratulated on providing the most comprehensive modern text in cardiovascular therapeutics. Instead of focusing narrowly on a single therapeutic modality—drugs, interventional cardiology, devices, or surgery—this contemporary, authoritative, and eminently readable book deals with *total* patient management. The several types of therapy that can be offered for specific cardiovascular disorders are presented lucidly and in sufficient detail to serve as the basis for managing the vast majority of patients with cardiovascular disease. This excellent text will be of immense value not only to cardiologists but also to internists and primary care physicians, who are shouldering increasing responsibilities for the management of patients with cardiovascular disease.

This third edition of *Cardiovascular Therapeutics* is essentially a new book when compared with its predecessor. There are three new Section Editors (Drs. James de Lemos, Michael Givertz, and Frank Sacks) and many new contributors. Forty-two of the 55 chapters are new or radically revised. The three appendices, on cardiovascular drugs, pacemakers and implantable cardioverter-defibrillators, and circulatory support devices, will be extremely useful.

We are very proud that *Cardiovascular Therapeutics* is a companion to *Heart Disease: A Textbook of Cardiovascular Medicine*. We hope that the new edition, along with the other books now available as companion volumes to *Heart Disease*, will serve as an extensive cardiovascular information system.

Eugene Braunwald, MD
Peter Libby, MD
Robert O. Bonow, MD
Douglas P. Zipes, MD

Preface

This third edition of *Cardiovascular Therapeutics*, a text originally proposed by the late Thomas Woodward Smith as a companion to *Heart Disease*, continues to emphasize an evidence-based approach to therapeutic recommendations for management of the patient with cardiovascular disease. I had the privilege of working with an experienced group of Section Editors—Dr. James de Lemos, Dr. Michael Givertz, Dr. Mark Josephson, Dr. Suzanne Oparil, and Dr. Frank Sacks—in the preparation of the new edition. The reader is provided with cutting-edge recommendations for treatment of common problems such as ischemic heart disease, heart failure, dyslipidemia, dysrhythmias, hypertension, congenital heart disease, pericardial disease, cardiovascular disorders during pregnancy, and infective endocarditis.

For this edition of *Cardiovascular Therapeutics*, 16 chapters are completely new, and 33 chapters and the 3 appendices have been radically revised. The introductory chapter on tools for understanding the evidence that drives guidelines recommendations has important new information from contemporary clinical trials. Critical chapters on emerging therapeutics approaches such as gene therapy and stem cell therapy and the biology and clinical trial results with drug-eluting stents have been added. To assist the clinician in understanding the details of the development and approval of cardiovascular devices, representatives from the U.S. Food and Drug Administration have contributed a new chapter. Appendix 1, on cardiovascular drugs, has been updated to reflect the additions to the pharmacotherapeutic armamentarium. Appendix 2 presents invaluable tables, algorithms, and figures to guide the clinician through the process of selecting and monitoring devices for treating dysrhythmias. Appendix 3 has the latest information on intracorporeal and extracorporeal circulatory support devices.

Primary care physicians and cardiologists from across a range of training and experience will find this new edition of the book a critical resource for their practice. Once again, there are extensive cross-references to the seventh edition of *Heart Disease* (designated HD7e in this textbook), edited by Douglas Zipes, Peter Libby, Robert Bonow, and Eugene Braunwald. By using *Cardiovascular Therapeutics* along with HD7e and the other books in the companion series in a synergistic fashion, clinicians will be able to make the most of an extraordinarily rich set of resources that have been rigorously prepared.

Acknowledgments

A new edition of a text such as *Cardiovascular Therapeutics* provides an opportunity to acknowledge the contributions of many individuals. The continued training in rigorous scientific thinking and clinical medicine provided by Eugene Braunwald is a treasured experience for which I am extremely grateful. The scientific and personal collaborations with Joseph Loscalzo have been an important asset in framing my thinking in preparing this edition. I wish also to acknowledge the generations of Cardiovascular Division Fellows and extraordinary faculty at the Brigham and Women's Hospital, under the leadership of Peter Libby, who provided the inspiration and professional environment for my work on *Cardiovascular Therapeutics*. A special note of gratitude is due to my colleagues in the TIMI Study Group, many of whom have contributed both directly and indirectly to this text. Sylvia Judd, my administrative assistant, continues to be an invaluable resource in countless ways related to the preparation and production of this book.

Finally, on behalf of all of the Section Editors and contributors, I wish to express appreciation for the efforts of the team at Elsevier who worked diligently to publish this text.

Elliott M. Antman, MD

SECTION 1

Decision-Making and Therapeutic Strategies in Cardiovascular Medicine

Chapter 1

Tools for Assessment of Cardiovascular Tests and Therapies

Elliott M. Antman, Robert M. Califf, and Joel Kupersmith

CHAPTER CONTENTS

Therapeutic decision-making in cardiovascular medicine should proceed through an orderly sequence of events beginning with elicitation of the pertinent medical history and performance of a physical examination (see Chapters 7 and 8 of *Heart Disease*, 7th ed.). In the ideal situation, a variety of diagnostic tests are ordered and the results are integrated into an assessment of the probability of a particular cardiac disease state. Based on this information and an assessment of the evidence to support various treatments, a therapeutic strategy is formulated. The purpose of this chapter is to provide an overview of the quantitative tools used to interpret diagnostic tests, evaluate clinical trials, and select a treatment plan. The principles and techniques discussed serve as a foundation for placing the remainder of *Cardiovascular Therapeutics* in perspective and serve as the foundation for the generation of guidelines for clinical practice.[1] Appropriate application of the therapeutic decision-making tools that are described and adherence to the guideline documents based on the tools translate into improved patient outcomes—an area where cardiovascular specialists have distinguished themselves among the various medical specialties.[2-5]

INTERPRETATION OF DIAGNOSTIC TESTS

A useful starting point for interpreting a diagnostic test is the standard 2 × 2 table describing the presence or absence of disease (as determined by a gold standard) and the results of the test.[6] Even before the results of the test are known, clinicians should estimate the pretest likelihood of disease based on its prevalence in a population of patients with clinical characteristics similar to the patient being evaluated. Because no diagnostic test is perfect, a variety of statistical terms are used to describe its operating characteristics (Fig. 1–1). *Sensitivity* is the proportion of patients with the disease who have a positive test. *Specificity* is the proportion of patients without the disease who have a negative test. The probability that a test will be negative in the presence of disease is the *false-negative rate,* and the probability that a test will be positive in the absence of disease is the *false-positive rate.* Other useful terms are *positive predictive value,* which describes the probability that the disease is present if the test is positive, and *negative predictive value,* which describes the probability that the disease is absent if the test is negative. The STARD (Standards for Reporting of Diagnostic Accuracy) initiative sets forth guidelines on how studies of reports on diagnostic accuracy should be prepared.[7]

Because the results of diagnostic tests are dependent on the profiles of patients being studied, the *likelihood ratio* has been introduced to express how many times more (or less) likely a test result is to be found in patients with disease compared with those without disease (see Fig. 1–1).[8] (This is analogous to Bayes' rule, in which one updates the prior probability of a disease state based on the conditional probability of the observed test result to form a revised or post-test probability of a disease state). By multiplying the pretest odds of disease by the likelihood ratio, clinicians can establish a post-test likelihood of disease and determine whether that likelihood

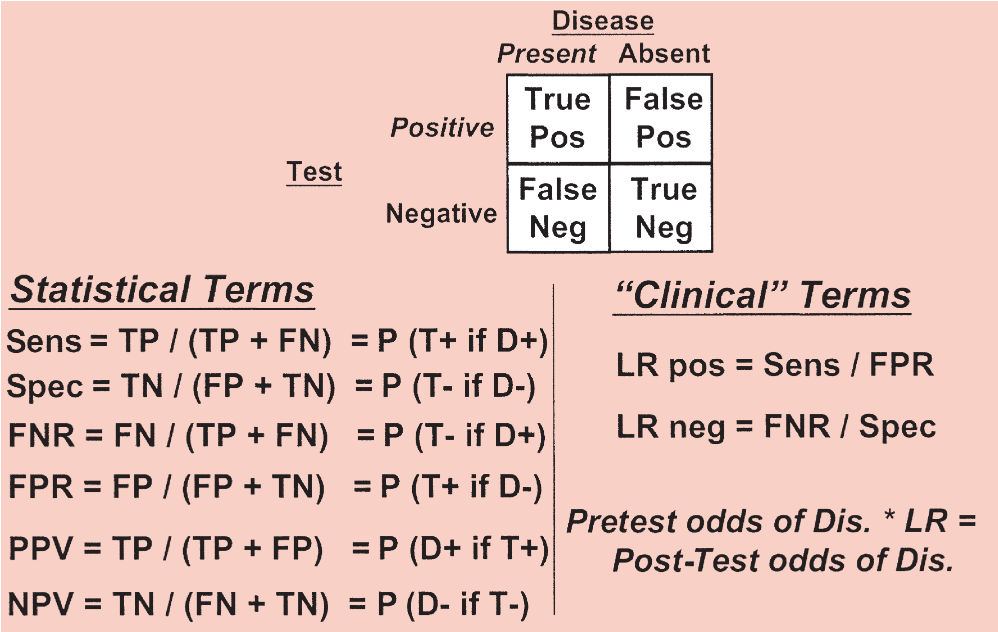

Figure 1–1 Interpretation of diagnostic tests. The standard 2 × 2 table (*top*) assigns patients into one of four cells based on the presence or absence of disease (according to a gold standard) and the results of a diagnostic test (positive or negative). Seven commonly used statistical terms that describe the operating characteristics of the test are given (*bottom left*). A clinically useful term is *likelihood ratio,* which expresses how many times a test result is more or less likely to be found in patients with disease compared with those without disease. This enables clinicians to update their pretest estimate of the odds of disease (Dis) and formulate a post-test odds of disease. The statistical terms can be interpreted along the lines of the following example: Sensitivity = probability (P) that the test is positive (T+) if the disease is present (D+). False Neg (FN), false negative; False Pos (FP), false positive; FNR, false-negative rate; FPR, false-positive rate; LR, likelihood ratio; NPV, negative predictive value; PPV, positive predictive value; Sens, sensitivity; Spec, specificity; True Neg (TN), true negative; True Pos (TP) true positive.

crosses the threshold for treatment.[9] For example, in a patient with chest discomfort, the presence of ST-segment elevation on the 12-lead ECG (diagnostic test) not only increases the probability that myocardial infarction (MI [disease state]) is present but also moves the decision-making process to the treatment threshold for reperfusion therapy without the necessity for further diagnostic testing. In the same patient, a nondiagnostic electrocardiogram does not appreciably alter the post-test likelihood of an MI. Additional testing (e.g., biomarkers of cardiac damage) is needed to establish the diagnosis of MI.

The example shown in Figure 1–1 is for a diagnostic test that produces dichotomous results—either positive or negative. Many tests in cardiology provide results on a continuous scale. Typically, diagnostic cutoffs are established based on tradeoffs between sensitivity and specificity. In the example shown in Figure 1–2, a diagnostic cutoff in the region of point A would have high sensitivity because it identifies the majority of patients with disease (true-positive results), but it does so at the expense of reduced specificity because it falsely declares the test to be abnormal in patients without disease. Using a range of diagnostic cutoffs for a positive test (e.g., see Fig. 1–2A to C), a receiver operating characteristic (ROC) curve can be plotted to illustrate the relation between sensitivity and (1-specificity).[9] Better tests are those in which the ROC curve is positioned close to the top left corner. Comparison between two tests over a range of diagnostic cutoffs is accomplished by calculating the area under the ROC curve; the test with the larger area is considered superior.[9] In practice, it is difficult for many clinicians to apply the quantitative concepts illustrated in Figure 1–2 at the bedside. This has led many laboratories to provide annotated reports to assist practitioners in forming a probabilistic estimate of the likelihood of a disease state being present.

CLINICAL TRIALS

Need for Clinical Trials

Therapeutic recommendations for various cardiovascular diseases discussed in this text have been formulated after intensive clinical investigation. Uncontrolled observational studies of populations provide valuable insight into pathophysiology and serve as the source for important hypotheses regarding the potential value of particular interventions. However, it is a rare therapy in medicine that has the dramatic effectiveness of penicillin for pneumococcal pneumonia so that epidemiologic data alone are sufficient for scientific acceptance and adoption into clinical practice. In view of the variability of the natural history of cardiovascular illnesses and the wide range of individual responses to interventions, clinical investigators, representatives of regulatory agencies, and practicing physicians have come to recognize the value of

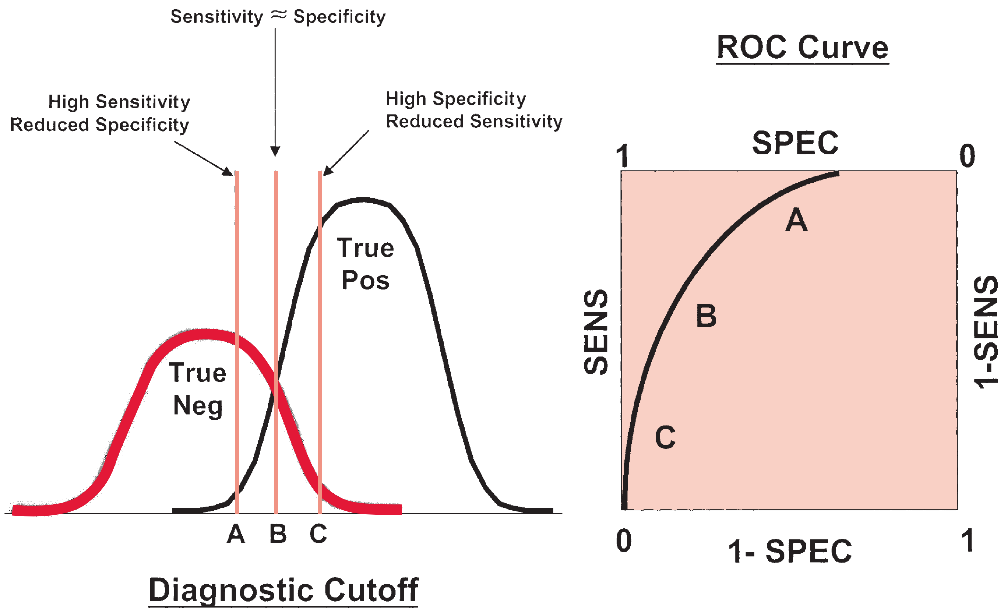

Figure 1–2 Influence of diagnostic cutoffs on interpretation of test performance. *Left*, Distributions of patients for whom the disease is present (True Pos) and the disease is absent (True Neg). Three different levels of a diagnostic cutoff (A to C) are shown for a test that is reported on a continuous scale. Diagnostic cutoff A has high sensitivity (identifies the majority of true-positive patients), although it does so at the expense of reduced specificity (a large number of true-negative patients are classified as having disease). At the other extreme, diagnostic cutoff C has high specificity (few true-negative patients classified as having disease) but at the expense of reduced specificity (a large proportion of true-positive patients are not classified as having disease). *Right*, Typical receiver operator characteristic (ROC) curve, illustrating the impact of cutoff levels A to C with respect to sensitivity (SENS) and specificity (SPEC).

Table 1–1 Phases of Evaluation of New Therapies

Phase	Features	Purpose
I	First administration of a new therapy to patients	Exploratory clinical research to determine if further investigation is appropriate.
II	Early trials of new therapy in patients	Designed to acquire information on dose-response relationship, estimate incidence of adverse reactions, and provide additional insight into pathophysiology of disease and potential impact of new therapy.
III	Large-scale comparative trial of new therapy versus standard of practice	Definitive evaluation of new therapy to determine if it should replace current standard of practice. Randomized controlled trials required by regulatory agencies for registration of new therapeutic modalities.
IV	Monitoring of use of therapy in clinical practice	Post "marketing" surveillance to gather additional information on impact of new therapy on treatment of disease. Rate of use of new therapy and more robust estimate of incidence of adverse reactions established from registries.

a control group and a rigorously performed clinical trial before widespread acceptance of a treatment.[10] The sequence of phases for the evaluation of new therapies is seen in Table 1–1.

Cardiovascular medicine has made a transition from practice based in large part on nonquantitative pathophysiological reasoning to practice oriented around "evidence-based medicine."[1] The importance of this concept has been reinforced by demonstration in clinical trials that widely accepted concepts have been associated with a substantial adverse effect on mortality rates. Type I antiarrhythmic drugs were often prescribed because of frequent premature beats until the Cardiac Arrhythmia Suppression Trial (CAST) demonstrated that such treatment increased the risk of death.[11] Despite the recognized importance of empirical evidence in guiding therapeutic decision-making, only with the advent of powerful computers have computational and organizational capabilities begun to meet researchers' needs.

Despite current limitations, evidence-based therapeutic recommendations that involve drugs, devices, and procedures

are in demand, with managed care, cost-saving measures, and guidelines published by authoritative groups playing increasingly prominent roles in the fabric of clinical medicine.[12] With the increasing number of elderly patients in the population, there also is a clear need for improved information on their response to therapeutic interventions.[13] Thus, the proper design, conduct, analysis, interpretation, and presentation of a clinical trial form an “indispensable ordeal” for investigators.[14,15] Over the last several years, a number of scandals related to clinical trials have occurred, leading to public distrust of the clinical trial process.[16,17] One solution that has been put in place is a mandate that clinical trials be registered in a public domain-accessible website; examples of a clinical trial registration data set have also been published.[18,19] Practitioners must also acquire the tools to critically read reports of clinical trials and, when appropriate, to translate the findings into clinical practice without the lengthy delays that occurred in the past. This is an especially important task for generalist physicians because of the increased emphasis on primary care physicians to control health care costs by managing chronic disease with appropriate testing and referral. In addition, there is evidence that generalist physicians are less aware, or less certain of the results, of clinical trials than are specialists.[20]

The sheer volume and broad range of clinical trials in cardiology are too large for even the most conscientious individual to digest on a regular basis. This has stimulated increased interest in biostatistical techniques to combine the findings from randomized controlled trials (RCTs) of the same intervention into a meta-analysis or an overview.[21]

Clinical Trial Design

Because of the importance of clinical trial findings, it is essential that investigators thoughtfully formulate the scientific question to be answered and have realistic estimates of the sample size required to show the expected difference in treatments. Trials that conclude there is no statistically significant difference between treatment A and treatment B are often undersized and lack sufficient power to detect a difference when one truly exists. A well-coordinated organizational structure, consisting of experienced trialists, biostatisticians, and data analysts, is important to prevent such pitfalls in trial design such as unrealistic assessments of the ease of patient recruitment and timetable for completion of the trial.

The stages of a clinical trial are summarized in Table 1–2. These should be viewed as a rough guide to the orderly sequence of events that characterizes the clinical trial process. The dividing lines between stages are often indistinct. For example, sites at which patients are randomized may be brought into the trial in a rolling fashion so that some of the features of the protocol–development stage may overlap with the patient–recruitment phase. It is possible that some of the

Table 1–2 Stages of a Clinical Trial

Stage	Activities During Stage	Event Marking End of Stage
Initial design	Formulation of scientific question, outcome measures established, sample size calculated	Initiation of funding
Protocol development	Trial protocol and manual of operations written, case report forms developed, data management systems and monitoring procedures established, training of clinical sites completed	Initiation of patient recruitment
Patient recruitment	Channels for patient referrals established, development of regular monitoring procedures of trial data for accuracy, patient eligibility, and site performance; preparation of periodic reports to DSMB for review of adverse or beneficial treatment effects	Completion of patient recruitment
Treatment and follow-up	Continued monitoring of patient recruitment, adverse effects and site performance; updated trial materials sent to enrolling sites; reports sent to DSMB and recommendations reviewed; adverse event reports filed with regulatory agency; timetable for trial close-out procedures established	Initiation of close-out procedures
Patient/trial close-out	Identification of final data items that require clarification so data base can be “cleaned and locked”; initiation of procedures for unblinding of treatment assignment, termination of study therapy, and monitoring of adverse events following discontinuation of treatment; preparation of final reports to DSMB; preparation of draft of final trial report	Completion of close-out procedures
Termination	Verify that all sites have completed close-out procedures including disposal of unused study drugs; review final trial findings and submit manuscript for publication; submit final report to regulatory agency.	Termination of funding for original trial
Post-trial follow-up (optional)	Recontact enrolling sites to acquire long-term follow-up on patients in trial; link follow-up data with initial trial data and prepare manuscript summarizing results.	Termination of all follow-up

DSMB, data safety monitoring board.

early sites that enroll patients gain sufficient experience with the protocol to achieve different results than those of the sites that join the trial later. Evidence of this phenomenon is typically sought by performing a test for interaction between the enrolling site and treatment effect when the data are analyzed. The situation can rapidly become quite complex when international differences in treatment effect are observed—especially if benefit is noted predominantly in one international region and not in others.[22] Of note, even after a fully executed development sequence from phase I through phase III trials, important adverse consequences of a new treatment may not be apparent. Although post-marketing (phase IV) trials (see Table 1–1) are theoretically supposed to catch such problems and identify treatments that should be withdrawn from clinical use, such trials are rarely conducted and several authorities have called for renovation of the drug regulation process to protect the population from harmful therapies.[23]

The term *control group* refers to those subjects in a clinical trial who receive the treatment against which the test intervention is being compared. Requirements for the control and test treatments are outlined in Table 1–3. *Randomized controlled trials* typically incorporate both test and control treatments and are considered the gold standard for the evaluation of new therapies. However, the previously noted definition of a control does not require that the treatment be a placebo, although frequently this is the case, because new treatments may have to be compared with the current standard of practice to determine whether they are more efficacious (e.g., new antithrombin agents versus unfractionated heparin; see Chapters 5 and 10) or within a range of effectiveness deemed to be clinically not inferior (e.g., bolus thrombolytic versus accelerated infusion regimen of alteplase; see Chapters 5 and 11).[6] This definition does not require that the control group be a collection of subjects distinct from the treatment group studied contemporaneously and allocated by random assignment. Other possibilities include nonrandomized concurrent and historical controls, crossover designs and withdrawal trials, with each patient serving as a member of both the treatment and control groups, and group or cluster allocations, in which groups of subjects or a treatment site is assigned as a block to either test or control.[6]

Table 1–3 Requirements for the Test and Control Treatments

They must be distinguishable from one another.
They must be medically justifiable.
There must be an ethical base for use of either treatment.
Use of the treatments must be compatible with the health care needs of study patients.
Either treatment must be acceptable to study patients and to physicians administering them.
There must be a reasonable doubt regarding the efficacy of the test treatment.
There should be reason to believe that the benefits will outweigh the risks of treatment.
The method of treatment administration must be compatible with the design needs of the trial (e.g., method of administration must be the same for all the treatments in a double-blind trial) and should be as similar to real-world as practicable.

Reproduced from Meinert C. Clinical Trials. Design, conduct, and analysis. New York, Oxford University Press, 1986, p 469.

Two broad types of controlled trials exist: the *fixed sample size design*, in which the investigator specifies the necessary sample size before patient recruitment, and the *open or closed sequential design*, in which sequential pairs of patients are enrolled (one to test and one to control) only if the cumulative test-control difference from previous pairs of patients remains within prespecified boundaries.[14] The sequential trial design is usually less efficient than the fixed sample size design and is practical only in situations in which the outcome of interest can be determined soon after enrollment. In addition, trials with the fixed design can be organized in a manner in which randomization and/or follow-up continues until the requisite number of endpoints is reached, thus ensuring that inadequate numbers of endpoints will not hamper the trial interpretation.

Case-control studies that involve a comparison of persons with a disease or outcome of interest (*cases*) with a suitable group of subjects without the disease or outcome (*matched controls*) are integral to epidemiologic research, are not strictly clinical trials, and are not discussed in this chapter.[24]

Randomized Controlled Trials

The RCT is the standard against which all other designs are compared for several reasons.[15] In addition to the advantage of incorporating a control group, this type of trial centers around the process of randomization, which has the following three important influences:

1. It reduces the likelihood of patient selection bias in allocation of treatment that may occur either consciously or unconsciously.
2. It enhances the likelihood that differences between groups are random so that comparable groups of subjects are compared, especially if the sample size is sufficiently large.
3. It validates the use of common statistical tests such as the χ^2 test for a comparison of proportions and Student's *t* test for a comparison of means.[9]

Randomization may be fixed over the course of the trial or may be adaptive based on the distribution of prior randomization assignments, baseline characteristic frequencies, or observed outcomes.[25] Fixed randomization schemes are more common and are specified further according to the allocation ratio (uniform or nonuniform assignment to study groups), stratification levels, and block size (i.e., constraining the randomization of patients to ensure a balanced number of assignments to the study groups, especially if stratification is used in the trial). Ethical considerations related to randomization have been the subject of considerable discussion in clinical trial literature.[26,27]

Clinicians usually participate in an RCT if they feel sufficiently uncertain about the potential advantages of the test treatment and can confidently convey this uncertainty to the patient, who must provide informed consent.[28] It is important that clinicians realize that in the absence of rigorously obtained data, many therapeutic decisions believed to be in the best interest of the patient may be ineffective or even harmful. To identify the appropriate therapeutic strategies from a societal perspective, RCTs are needed.

A difficult philosophical dilemma arises when one considers that as patients are enrolled in a trial, evidence is

accumulating that tends to favor one study group over the other, and the degree of uncertainty about the likelihood of benefit or harm is constantly being updated. Because clinicians may feel uneasy about enrolling a patient who may be randomized to a treatment that the accumulating data suggest might be inferior but has not yet been proved statistically to be so with a conventional level of significance, the outcome data from the trial are not revealed to the investigators during the patient recruitment stage. The responsibility of safeguarding the welfare of patients enrolled in the trial rests with an external monitoring team referred to as a *Data Safety Monitoring Board* (DSMB) or *Data Safety Monitoring Committee* (DSMC).[27,29-32] Several prominent examples of the early termination of large RCTs because of compelling evidence of benefit or harm from one of the treatments under investigation are evidence that the DSMB has become an integral element of clinical trial research.[33]

When both the patient and the investigator are aware of the treatment assignment, the trial is said to be *unblinded*. Trials of this nature have the potential for bias, particularly during the process of data collection and patient assessment, if subjective measures such as the presence or absence of congestive heart failure are tabulated.[27] In an effort to reduce bias, progressively stricter degrees of blinding may be introduced. Single-blind trials mask the treatment from the patient but permit it to be known by the investigator; double-blind trials mask the treatment assignment from both the patient and investigator; and triple-blind trials also mask the actual treatment assignment from the DSMB and provide data only in the form of group A and group B.

The specialty of cardiology is replete with examples of RCTs. An area particularly rich in this regard is the study of treatments for ST-elevation MI (see Chapter 11), in which several types of RCTs have been performed. These trials have been broadly classified into minitrials and megatrials. A further subdivision of the minitrials includes those that are of limited sample size and focus almost exclusively on mechanistic data and those with a sample size an order of magnitude larger and hybrid goals focusing on mechanistic data as they relate to mortality. Because of the practical limitations of the very large sample size required when mortality is used as the primary endpoint in trials of new cardiovascular therapies, the majority of which are expected to have a treatment effect of 15% to 20%, interest has arisen in the use of composite endpoints such as the sum of death, nonfatal recurrent MI, and recurrent ischemia as the primary endpoint.[34] Trials that use composite endpoints, especially those that involve sophisticated biological measurements (e.g., ejection fraction ascertained by radionuclide ventriculography), are more likely to have missing data than are those that use mortality as the primary endpoint. This ascertainment bias or noninformative censoring of the data may necessitate statistical adjustments to compensate for missing data.[35]

Nonrandomized Concurrent Control Studies

Trials in which the investigator selects the subjects to be allocated to the control and treatment groups are *nonrandomized concurrent control studies*. The advantages of this simpler trial design are that clinicians do not leave to chance the assignment of treatment in each patient and there is no need for patients to accept the concept of randomization. Implicit in this design type is the assumption that the investigator can appropriately match subjects in the test and control groups for all relevant baseline characteristics. This is a difficult task and can produce a selection bias that may result in conclusions that differ in direction and magnitude from those obtained from RCTs.[36]

Observational analyses contain many of the same structural characteristics as randomized trials except that the treatment is not randomized. These studies should have prospectively collected data with uniform definitions managed by a multidisciplinary group of investigators that include clinicians, biostatisticians, and data analysts. Outcomes must be collected in a rigorous and unbiased fashion, just as in the randomized trial.

Historical Controls

Clinical trials that use historical controls compare a test intervention with data obtained earlier in a *nonconcurrent, nonrandomized control group*. Potential sources for historical controls include previously published medical literature and unpublished data banks of clinic populations. The use of historical controls allows clinicians to offer potentially beneficial therapies to all subjects, thereby reducing the sample size for the study. The major drawbacks are bias in the selection of the control population and failure of the historical controls to reflect contemporary diagnostic criteria and concurrent treatment regimens for the disease under study.

It should be noted, however, that prospectively recorded registry data may be more representative of actual clinical practice than the control groups in RCTs. Notable examples include the National Registry of Myocardial Infarction (NRMI) and CRUSADE registries in the United States and international registries such as GRACE (Global Registry of Acute Coronary Events). Reports from such registries are useful for identifying gaps in translation of therapies proven to be effective in clinical trials into routine practice.[37]

Crossover Design

The crossover design is a special case of the RCT, in that each subject serves as his or her own control. A simple, two-period, crossover design randomly assigns each subject to either the test or control group in the first period and to the alternative in the second period. The appeal of this design is the ability to use the same subject for both test and control treatments, thereby diminishing the influence of inter-individual variability and allowing a smaller sample size. However, important limitations to crossover design are the assumptions that the effects of the treatment assigned during the first period have no residual effect on the treatment assigned during the second period and that the patient's condition remains stable during both periods. The validity of these assumptions is often difficult to verify either clinically or statistically (e.g., testing for an interaction between period and intervention), leading some authorities to discourage the use of crossover designs. One possible use of the crossover trial design is the preliminary evaluation of new antianginal agents for patients with chronic, stable exertional angina.[38]

Withdrawal Studies

In withdrawal studies, patients with a chronic cardiovascular condition are taken off therapy or undergo a reduction in dosage. The goal is to evaluate the response to discontinuation

of treatment or reduction in its intensity. An important limitation is that only patients who have tolerated the test intervention for a period of time are eligible for enrollment, because those with incapacitating side effects would have been taken off the test intervention and are, therefore, not available for withdrawal. This selection bias can overestimate benefit and underestimate toxicity associated with the test intervention. In addition, changes in the natural history of the disease may influence the response to withdrawal of therapy. For example, if a therapeutic intervention is beneficial early after the onset of the disease but loses its benefit over time, the withdrawal of therapy late in the course of treatment might not result in deterioration of the patient's condition. A conclusion that the intervention was not helpful because its withdrawal during the chronic phase of treatment did not result in a worsening of the patient's condition provides no information about the potential benefit of treatment in the acute phase or subacute phase of the illness. Withdrawal trials can provide clinically useful information but they should be conducted with the same standards that are applied to controlled trials of prospective treatment, including randomization and blinding, if possible.

The following withdrawal trial in cardiology illustrates many of the features discussed previously. Although digitalis has been used by physicians for more than 200 years, its benefits for the treatment of chronic congestive heart failure, particularly in the patient with normal sinus rhythm, remain controversial. To assess the consequences of withdrawing digoxin from clinically stable patients with New York Heart Association functional class II to III congestive heart failure who are receiving angiotensin converting enzyme inhibitors, the *R*andomized *A*ssessment of [the effect] *D*igoxin [in patients] on *I*nhibitors of the *AN*giotensin-*C*onverting *E*nzyme (RADIANCE) investigators randomly allocated 178 patients in a double-blind manner to continue to receive digoxin or to switch to a matched placebo.[39] Worsening heart failure necessitating discontinuation from the study occurred in 23 patients who were switched to placebo but in only 4 patients who continued to receive digoxin ($P < 0.001$). The results of the RADIANCE trial seem to indicate that withdrawal of digoxin in patients with mild-to-moderate congestive heart failure as a result of systolic dysfunction is associated with adverse consequences, but it does not provide information on the potential mortality benefit of digoxin when *added* to a regimen of diuretics and angiotensin-converting enzyme inhibitors.[40] The Digitalis Investigation Group (DIG) Trial, a classic RCT, showed that digoxin therapy was not associated with a mortality benefit but did provide symptomatic improvement in that it reduced the need for hospitalization for decompensated congestive heart failure.[41]

Factorial Design

When two or more therapies are tested in a clinical trial, investigators typically consider a *factorial design*, in which multiple treatments can be compared with control through independent randomization within a single trial. A schematic example of a 2 × 2 factorial design trial is shown in Figure 1–3. In this example, 10,000 patients are randomized to receive two interventions (drug A and drug B). There are four categories of patients: active A/active B, placebo A/active B, active A/placebo B, placebo A/placebo B. These groups of patients allow assessment of the treatment effect of drug A in the absence of drug B (difference 1) and in the presence of drug B (difference 2). A grand summary (pooled) statement of the treatment effect of drug A can be made, along with a measure of the interaction of coadministration of drug B and drug A. A similar and symmetrical analysis can be performed for drug B. This line of reasoning may be extended to more than two test treatments—as was the case in the fourth International Study of Infarct Survival (ISIS-4), in which three interventions (i.e., captopril, nitrates, and magnesium) were evaluated in a 2 × 2 × 2 factorial design, and patients fell into one of eight separate categories.[42]

Factorial design trials are more easily interpreted when there is believed to be no interaction between the various test treatments—as is often the case when drugs have unrelated mechanisms of action. If no interactions exist, multiple drug comparisons can be efficiently performed in a single large trial that is smaller than the sum of two independent clinical trials. When interactions are detected, each intervention must be evaluated individually against a control and each of the other interventions in which an interaction exists.

Biostatistical Tools for Comparing Therapies for Acute Coronary Syndromes

Use of Factorial Design to Evaluate Drug Interactions

Total Enrollment = 10,000 patients

	Active A 5000	*Placebo A* 5000
Active B 5000	Active A Active B 2500	Placebo A Active B 2500
Placebo B 5000	Active A Placebo B 2500	Placebo A Placebo B 2500

Evaluation of drug A alone and in combination with drug B:

Active A / Placebo B vs Placebo A / Placebo B = $\text{Difference}_1 = D_1$

Active A / Active B vs Placebo A / Active B = $\text{Difference}_2 = D_2$

Treatment effect of drug A in the absence of drug B = D_1

Treatment effect of drug A in the presence of drug B = D_2

Grand summary of treatment effect of drug A = $D_1 + D_2$

Interaction of drug B on treatment effect of drug A = $D_2 - D_1$

Figure 1–3 Factorial design of clinical trial. *Top*, In this example, 10,000 patients are randomized to receive or not receive two interventions (drug A and drug B). Each patient will fall into one of the following four categories: Active A/Active B, Placebo A/Active B, Active A/Placebo B, Placebo A/Placebo B. *Bottom*, Differences in event rates for the comparisons permit an assessment of the treatment effect of drug A in the presence and absence of drug B. See text for further discussion. (Reproduced with permission from Antman EM: Medical therapy for acute coronary syndromes: An overview. In Califf R, Braunwald E [eds]: Acute Myocardial Infarction and Other Acute Ischemic Syndromes. Philadelphia, Current Medicine, 1996.)

The factorial design trial has an important place in cardiology, in which multiple therapies are typically given to the same patient for important conditions such as MI, heart failure, and secondary prevention of atherosclerosis, and so in practical terms, the factorial design is more reflective of actual clinical practice than trials in which only a single intervention is randomized. Clinicians need to know how much incremental value comes from the administration of one more drug to the patient and whether any drug interactions exist. It is worth noting, however, that it is probably an insurmountable task to rule out the possibility of a drug interaction because of the imprecision with which interaction effects are estimated (i.e., wide confidence intervals), the poor power of tests for statistical significance of interactions between the test interventions, and the vast number of non–protocol-related drugs a patient may receive. For example, in addition to the eight patient groups in the main design of ISIS-4, the type of fibrinolytic prescribed, the presence or absence of intravenous β-blockers, and the use of nontrial nitrates such as intravenous nitroglycerin, among other factors, rapidly escalate the number of patient cells to nearly 100.[42]

Trials That Test Equivalence of Therapies

Advances in cardiovascular therapeutics have dramatically improved the treatment of various diseases, such that several therapies of proven efficacy may coexist for the same treatment. However, it may still be desirable to develop new therapies that are equally efficacious but have an important advantage—such as reduced toxicity, improved patient tolerability, more favorable pharmacokinetic profile, fewer drug interactions, or lower cost.[43,44] Testing such new therapies using placebo-controlled trials poses problems on ethical grounds because one half of the patients would be denied treatment when an accepted therapy of proven efficacy exists.[28,45,46] This has led to a shift in clinical trial design to demonstrate therapeutic equivalence of two treatments rather than superiority of one of the treatments.[27,43,47,48] The concept of equivalence trials has a precedent in the study of bioequivalence, where, for example, two drug preparations are considered equivalent if they produce similar areas under the curve (AUCs) in plots of blood levels versus time.

It is not possible to show two active therapies to be completely equivalent without a trial of infinite sample size. Instead, investigators resort to specifying a value (δ) and consider the test therapy to be equivalent to the standard therapy if, with a high degree of confidence, the true difference in treatment effects is less than δ (Fig. 1–4A).[47,49]

The nomenclature related to trials of tests of equivalence between two therapies can be confusing. In a classic equivalence trial, if the confidence intervals for the estimate of the effects of the two treatments differ by more than the equivalence margin (i.e., δ) in either direction, then equivalence is said not to be present. For most clinical trials of new therapies, the objective is to establish that the new therapy is not worse than the standard therapy (i.e., active control) by more than δ.[45] Such one-sided comparisons are referred to as *noninferiority trials*.[43] The new therapy may satisfy the definition of *noninferiority* but, depending on the results, may or may not actually show superiority compared with the standard therapy.

Specification of the appropriate margin, or δ, is often problematic. Clinicians prefer to set δ based on a clinical perception of a minimally important difference they believe would affect their practice. Regulatory authorities, who are bound by a legal mandate "to show that drugs work," assess the effect of the standard therapy based on prior trials where it was compared with placebo. Rather than specifying the point estimate for the full effect of the standard therapy over placebo, a more conservative approach is taken by selecting the lower bound of a confidence interval for superiority of the standard therapy over placebo for setting the noninferiority margin.[45,50] Because the noninferiority margin is usually smaller than the treatment difference between an active control and placebo, the sample size of noninferiority trials is typically larger than for a superiority trial against placebo.

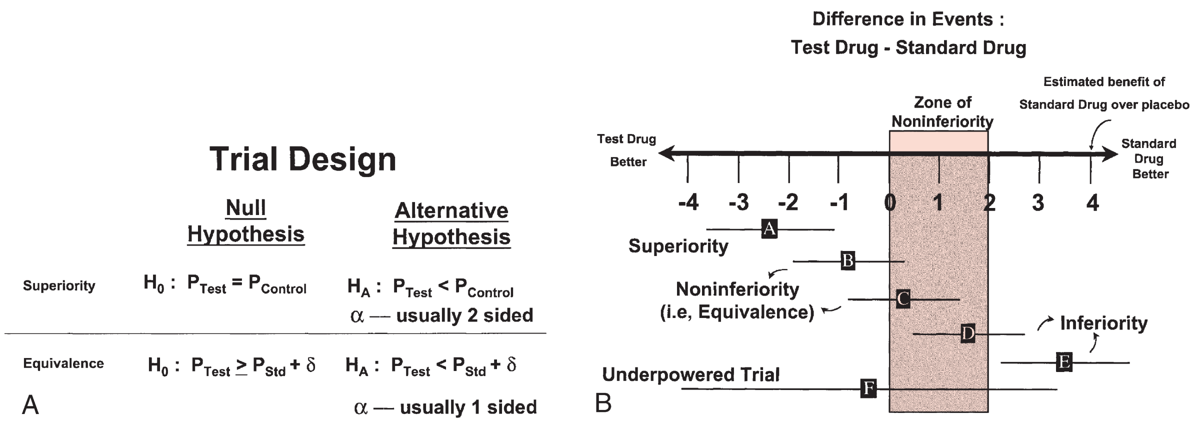

Figure 1–4 **A,** Statistical design of superiority and equivalence trials. In both superiority and equivalence trials, the investigators propose a null hypothesis (H_0) with the goal of the trial being to reject H_0 in favor of the alternative hypothesis (H_A). To determine whether the null hypothesis may be rejected, before initiation of the trial, the type I (α) and type II (β) errors are specified. In superiority trials, α is usually two sided, whereas it is usually one sided in equivalence trials. The quantity (1–β) is referred to as the power of the trial (*not shown*). Std = standard therapy. **B,** Example of design and interpretation of noninferiority trials. The zone of inferiority is prespecified based on prior trials comparing the standard drug with placebo. Examples of hypothetical trials A to F are shown, of which some satisfy the definition of noninferiority. See text for further discussion. (**B,** Redrawn from Antman EM: Clinical trials in cardiovascular medicine. Circulation 2001;103:E101-4.)

Figure 1–4B provides an example of the design of noninferiority trials and interpretation of six hypothetical trial results. In Figure 1–4B, the difference in events between the test drug and the standard drug is plotted along the horizontal axis. Based on trials against placebo, the standard drug provides a benefit over placebo at the +4 position, but the lower bound of its superiority over placebo is at the +2 position. Thus, the noninferiority margin is set at +2. The six hypothetical trials A to F are shown with the point estimate of the difference between the test drug and standard drug as filled squares and the width of the 95% CI for the difference as the thin horizontal lines. Because the results of trial A fall entirely to the left of 0 (i.e., the upper bound does not enter the zone of noninferiority), it is possible to declare the test drug to be superior to the standard drug. In the trials B and C, the upper bound falls within the zone of noninferiority, and in loose parlance, the test drug is declared to be "equivalent" to the standard drug. Note that in the cases of trials D and E, the noninferiority requirement is not satisfied (upper bound exceeds margin in trial D, and the entire confidence interval exceeds the margin in trial E), and the test drug is said to be inferior to the standard drug. It is important to prespecify the noninferiority margin before starting the trial because if it is specified after the results are known, the trial could be criticized owing to potential subjective bias. For example, if the results of trial D were known and the noninferiority margin was set at +3 rather than +2, the test drug would satisfy the definition of noninferiority but such an approach would be highly suspect. It is also important to have a sufficient sample size of the trial to draw meaningful conclusions. For example, although the point estimate for trial F is in favor of the test drug, the wide confidence intervals are due to a small sample size. Trial F does not allow the investigators to claim superiority of the test drug compared with the standard drug, and it would be inappropriate to claim it to be "equivalent" to the standard drug simply because superiority could not be demonstrated (note that the upper bound of trial F clearly exceeds the noninferiority margin).

Investigators can prespecify that a trial is being designed to test superiority and noninferiority simultaneously.[50,54] For a trial that is configured only as a noninferiority trial, it is acceptable to test for superiority at the conclusion of the trial. However, because of the subjective bias as mentioned, the reverse is not true—trials configured for superiority cannot later test for noninferiority unless the margin was prespecified.[50] An important commonality between superiority and noninferiority trials is that the clinical experts involved in trial design should consciously consider the minimally important clinical outcome difference. A common understanding of the difference between outcomes with two therapies forms the basis for providing the appropriate perspective on the interpretation of test statistics—in essence, the difference between "statistically significant" and "clinically important" is determined by the common view of the difference that would lead to a change in practice. Noninferiority trials, a more recent addition to the RCT repertoire, are prone to controversy, especially if there is disagreement over the noninferiority margin (i.e., the percentage of the treatment benefit of the gold standard therapy over placebo that would be retained by the new treatment and still be considered clinically equivalent).[51,51a] The reporting of noninferiority trials in the medical literature is often deficient, with failure to provide an adequate justification for the noninferiority margin or the sample size.[52] In a fashion similar to that for reporting a superiority trial, the CONSORT Group has published recommendations for a checklist and graphic display of the results of noninferiority trials.[53]

Selection of Endpoint

A critical decision when designing a clinical trial is the selection of the outcome measure. In trials comparing two treatments in cardiovascular medicine, the outcome measure (or endpoint of the trial) is characteristically a clinical event. The characteristics of an ideal primary outcome measure are that it is easy to diagnose, is free of measurement error, can be observed independent of treatment assignment, is clinically relevant, and should be selected prior to the start of data collection for the trial.[55] Because of their serious nature, the hard endpoints of mortality (all cause or cardiovascular) and nonfatal events such as myocardial infarction have traditionally been selected by cardiovascular investigators for definitive evaluation of new treatments, especially in registration pathway trials.[34,54]

Improvements in cardiovascular treatments have, gratifyingly, lead to a reduction in mortality rates and, therefore, a lower event rate in the control arm of clinical trials—with an attendant increase in the required sample size (see later). The desire to evaluate new therapeutic approaches in the face of rising costs to conduct large clinical trials has resulted in two major approaches to the selection of endpoints. The first is to use a composite endpoint combining mortality with one or more nonfatal negative outcomes such as myocardial infarction, stroke, recurrent ischemia, or hospitalization for heart failure.[56-59] Trials with a logical grouping of composite endpoints that are likely to each be affected by the treatments being studied are clinically valuable and have been used to advance treatments for heart failure and acute coronary syndromes.[15] However, interpretation of composite endpoints becomes problematic when elements of a composite endpoint go in opposite directions in response to treatment (e.g., reduced mortality but increased nonfatal MI). To date, there is no consensus on an appropriate weighting scheme for composite endpoints.[15]

Another approach is to use a surrogate endpoint as a substitute for clinical outcomes. A valid surrogate endpoint not only must be predictive of a clinical outcome but also evidence that modification of the surrogate endpoint captures the effect of a treatment on clinical outcomes because the surrogate is in the causal pathway of the disease process.[15] Examples of a successful surrogate endpoint and failed surrogate endpoints are schematically illustrated in Figure 1–5. Whether or not a surrogate endpoint is useful for determining if a treatment is efficacious, a single surrogate cannot be used to develop a balanced view of risk and benefit, particularly compared with alternative therapies. This increasingly recognized critical element of therapeutic development and evaluation requires measurement of clinical outcomes in the relevant population over a relevant period of time.

Sample Size Estimations and Sequential Stopping Boundaries

Estimation of the sample size for trials involves a statement of the scientific question in the form of a null hypothesis (H_0) and an alternative hypothesis (H_A). For example, in the case of

dichotomous variables (e.g., presence or absence of a primary outcome variable such as mortality), the null hypothesis states that the proportion of patients dying in the test group (P_{Test}) is equal to that in the control group ($P_{Control}$) (see Fig. 1–4A), such that for

$$H_0: P_{Test} - P_{Control} = 0$$

The alternative hypothesis is that for

$$H_A: P_{Test} - P_{Control} \neq 0$$

False-Positive and False-Negative Error Rates and Power of Clinical Trial

To determine whether the null hypothesis may be rejected, before initiation of the trial, the type I (α) and type II (β) errors, sometimes referred to as the *false-positive* and *false-negative rates*, are specified (see Fig. 1–4A). The conventional α of 5% indicates that the investigator is willing to accept a 5% likelihood that an observed difference as large as projected in the sample size calculation occurred by chance and would lead to rejection of the null hypothesis when, in fact, the null hypothesis was correct.[60] The β value reflects the likelihood that a specified difference might be missed or not found to be statistically significant because of an insufficient number of events in the trial at the time of analysis. The quantity (1–β) is referred to as the *power of the trial* and quantifies the ability of the trial to find true differences of a given magnitude between the groups. The relations among estimated event rates, the prespecified α level, and desired power of the trial determine the number of patients that must be randomized to detect the anticipated difference in outcomes according to standard formulas.[60] Similar concepts are applied to response variables that are not dichotomous but are measured on a continuous scale (e.g., blood pressure) or represent time to failure (e.g., Kaplan-Meier survival curves).[61]

Statistical methods are also available for monitoring a trial during the patient recruitment phase at certain prespecified intervals to determine whether the accumulated evidence strongly suggests an advantage of one treatment in the trial.[26] During such interim checks of the data, the differences between treatment groups expressed as a standardized normal statistic (Z_i) are compared with boundaries such as those shown in Figure 1–6. If the Z_i statistic falls outside the boundaries at an *i*th interim look, the DSMB may give serious consideration to recommending termination of the trial. Typically, the data are arranged as *test:control*, so crossing of the upper boundary denotes statistically significant superiority of the test therapy over control, and crossing of the lower boundary denotes superiority of the control therapy over the test therapy. Because of the considerable expense of large clinical trials, in some cases it may be desirable to discontinue a trial at an interim analysis if the accumulated data suggest the probability of a positive result—should the trial proceed to completion—has become quite low. A *futility index* that describes the likelihood of a positive result based on accumulated data has been developed, allowing investigators to discontinue a nonproductive trial and concentrate limited resources on alternative trial options.[63]

Considerable clinical and statistical wisdom is required of DSMB members because they must consider and integrate the consistency and timeliness of the trial data reviewed at each interim analysis, random variation in event rates during the course of the trial, the type and severity of the disease under study, the magnitude of the benefit versus the risks of the therapy being investigated, and emerging data from other trials and clinical experience.[64] The decision to stop an RCT early because of an apparent strong treatment benefit favoring one of the arms is complex. Although investigators, sponsors funding the trial, and journal editors are likely to become

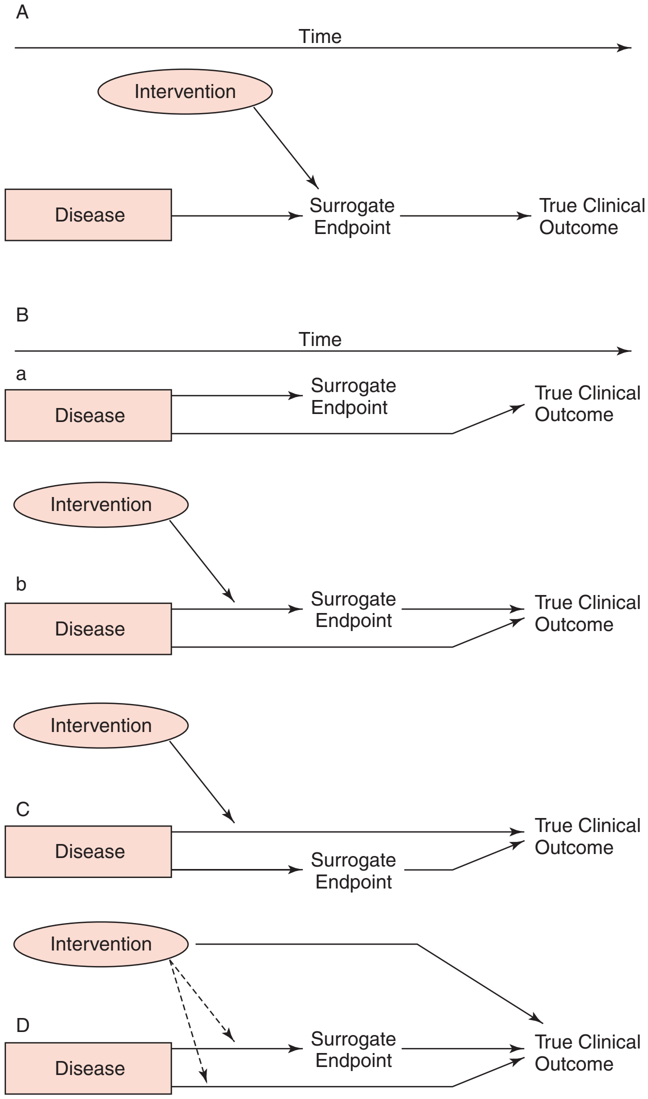

Figure 1–5 The setting that provides the greatest potential for the surrogate endpoint to be valid (a). Reasons for failure of surrogate endpoints (b). The surrogate is not in the causal pathway of the disease process (**A**). Of several causal pathways of disease, the intervention affects only the pathway mediated through the surrogate (**B**). The surrogate is not in the pathway of the intervention's effect or is insensitive to its effect (**C**). The intervention has mechanisms for action independent of the disease process (**D**). *Dotted lines* indicate mechanisms of action that might exist. caught up in the excitement and publicity surrounding an announcement of early stopping of a trial for benefit, it should be noted that there is a precedent for unrealistically large treatment effects to be disproved by subsequent RCTs.[65,66] A systematic review of RCTs stopped early for benefit reported that there is often a failure to report relevant information about the decision-making process and such decisions to stop an RCT early tend to provide unrealistic estimates of the true treatment benefit when the total number of events observed is small.[66] In the case of new, unapproved treatments, early stopping for benefit may place regulatory authorities in the uncomfortable position of not having enough safety data on which to base approval of the new treatment.[65]

Although it may occasionally appear that an extreme treatment effect is present in a particular subgroup, this must be interpreted cautiously to be certain that this effect is consistent with a prior hypothesis and remains significant after adjusting for multiple comparisons, interactions, and the interim nature of the analysis.[67] DSMB members must balance formal statistical stopping guidelines, ethical obligations to patients, common sense, and the obligation to the clinical community to ensure that the willingness of patients to consent to participation in the trial leads to an advance in the state of knowledge about the optimal therapeutic strategy.[31] For example, in 1989, the Beta-Blocker Heart Attack Trial was stopped early because of strong evidence of benefit from propranolol, especially in view of the previously published Norwegian Timolol Study.[31] In contrast, CAST was terminated early after the DSMB believed compelling evidence had accumulated indicating that, contrary to the prevailing clinical impression at the time, the suppression of ventricular premature beats with encainide or flecainide after MI was associated with increased mortality rates.[26]

A fascinating and controversial approach to the design, monitoring, and interpretation of clinical trials is the use of a Bayesian approach. Compared with the *classic* or *frequentist* approach described earlier, Bayesian methods formally use prior information specifying it as a prior probability distribution.[68] Instead of presenting the results of the trial in the form of *P* values and confidence intervals, Bayesian analysts present plots of the posterior distribution of the treatment effect. Interim monitoring procedures such as those shown in Figure 1–6 for the frequentist approach are replaced with posterior distribution plots. By employing a "skeptical" prior probability, a conservative approach to stopping rules can be developed according to Bayesian analysis. At present, the frequentist approach is the standard approach accepted by regulatory authorities for the approval of new therapies because of concerns about the sources and uncertainties regarding the prior probability distribution, but particularly with devices, flexibility on this matter is increasing. In the future, a Bayesian approach may be used more frequently in RCT design and analysis.

HOW TO READ AND INTERPRET A CLINICAL TRIAL

To properly interpret a clinical trial report and to apply it in their practice, clinicians must have a working knowledge of the statistical and epidemiologic terms used to describe the results. By asking three main sets of questions, such as those in Table 1–4 adapted from the McMaster Group, and by summarizing the trial findings as per the example in Figure 1–7, physicians will be equipped to integrate the information in manuscripts that describe clinical trials into their own practices.

One first determines that the study was of sufficient caliber to provide valid results, extracts the essential trial data, and enters it into a 2 × 2 table. In the example shown in Figure 1–7, 10,000 patients who met the enrollment criteria for a clinical trial were randomized with an allocation ratio of 1:1, so 5000 patients received treatment A and 5000 received treatment B. Because only 600 primary outcome events occurred in group A (12% event rate) and 750 occurred in group B (15% event rate), it appears that treatment A is more effective than treatment B.[6] Is this difference statistically significant, and is it clinically meaningful? When the data are arranged in a 2 × 2 table (see Fig. 1–7), a χ^2 test or Fisher exact test can be readily performed according to standard formulas.[9]

Although the investigators of the trial will likely have analyzed the results using one of the methods illustrated in Figure 1–7, it is useful to have a measure of the precision of the findings and an impression of the potential impact of the results on clinical practice. Even a well-designed clinical trial can provide only an estimate of the treatment effect of the test

Table 1–4 Questions to Ask When Reading and Interpreting the Results of a Clinical Trial

Are the Results of the Study Valid?

Primary Guides

1. Was the assignment of patients to treatment randomized?
2. Were all patients who entered the trial properly accounted for and attributed at its conclusion?
    - Was follow-up complete?
    - Were patients analyzed in the groups to which they were randomized?

Secondary Guides

1. Were patients, their clinicians, and study personnel "blind" to treatment?
2. Were the groups similar at the start of the trial?
3. Aside from the experimental intervention, were the groups treated equally?

What Were the Results?

1. How large was the treatment effect?
2. How precise was the treatment effect?

Will the Results Help Me in Caring for My Patients?

1. Does my patient fulfill the enrollment criteria for the trial? If not, how close is my patient to the enrollment criteria?
2. Does my patient fit the features of a subgroup in the trial report? If so, are the results of the subgroup analysis in the trial valid?
3. Were all the clinically important outcomes considered?
4. Are the likely treatment benefits worth the potential harm and costs?

Are the Results of the Study Valid? JAMA 1993;270:2598-2601 and Guyatt GH, Sackett DL, Cook DJ: The Medical Literature: Users' Guides to the Medical Literature: II. How to Use an Article About Therapy or Prevention: B. What Were the Results and Will They Help Me in Caring for My Patients? JAMA 1994;271:59-63.

intervention owing to random variation in the sample of subjects studied, who are selected from the entire population of patients with the same disease. The imprecision of the statement regarding treatment effect can be estimated and incorporated into the presentation of the trial results by calculating the 95% CIs around the observed treatment effect.[69] If the 95% CIs are not reported in the trial, inspection of the *P* value may be useful to indicate whether the confidence interval spans a null effect. Alternatively, the 95% CIs may be estimated as the treatment effect plus or minus twice the standard error of the treatment effect (if reported) or calculated directly.[69]

Measures of Treatment Effect

When the outcome is undesirable and the data are arranged as test group:control group, a relative risk (RR) or odds ratio (OR) of less than 1 indicates benefit of the test treatment. The relative risk of 0.80 (95% CI, 0.72 to 0.88) and odds ratio of 0.77 (95% CI, 0.69 to 0.87) in Figure 1–7 are indicative of benefit associated with treatment A.[6] When the control rate is low, the OR will approximate the RR, and the OR may be thought of as an estimator of the RR. As the control rate increases, the OR deviates further from the RR, and clinicians should rely more on the latter. The *treatment effect*, expressed as an RR reduction in this example, is 20%, but its 95% CI ranges from 12% to 28%. Such statements should be interpreted in the context of the absolute risk of the adverse outcome it is designed to prevent. The *absolute risk difference* (ARD) is even more meaningful if expressed as the number of patients that must be treated (=1/ARD) to observe the beneficial effect if it is as large as reported in the trial.[70]

If practitioners are given clinical trial results only in the form of RR reduction, they tend to perceive a greater effectiveness of the test intervention than if a more comprehensive statement is provided, including ARD and the number needed to treat.[71] Thus, in light of the baseline risk of 15% in the control group (a value that might represent the 1-month mortality of contemporary patients with MI not treated with fibrinolytic agents), the 12% event rate in the test group represents an ARD of 3%, which corresponds to 1/0.03 or approximately 33 patients who require treatment to prevent the occurrence of one adverse event. This statement is sometimes given as the number of lives saved per 1000 patients treated, corresponding to 30 lives in this example. Against this benefit must be weighed the risks associated with treatment (e.g., hemorrhagic stroke with fibrinolytic therapy for MI), which can be expressed as the *number needed to harm* (NNH = 1/ARI, where ARI is the absolute increase in events in the treatment group).[72] A composite term referred to as *net clinical benefit* has been introduced to incorporate both benefit and harm. In this example, if treatment A is associated with a 0.5% excess risk of an adverse outcome, such as stroke, compared with treatment B, then for every 1000 patients who receive treatment A, 30 lives would be saved at the expense of five strokes, for a net clinical benefit of 25 stroke-free lives saved.

These types of comparisons require the clinical community to make a judgment regarding the relative importance of various outcomes. How many deaths have to be prevented to offset one stroke? Another example is the possibility that some therapies (inotropic agents) may improve symptoms but at the same time may increase mortality rates, a scenario that may be acceptable to patients incapacitated by severe symptoms but not to patients with mild symptoms.[15] This issue can be explicitly addressed with the use of decision analysis (see Decision Analysis section).

The *number needed to treat* is a complex concept that becomes even more difficult when the impact of therapies for chronic disease are considered. For acute therapies with only a short-term effect, such as thrombolytic therapy, the simple version of number needed to treat is adequate. However, saving 10 lives per 100 patients treated in the first 30 days is quite different from the same effect over 5 years. In some therapies, the concept is even more complex, because the more effective treatment may have an early hazard—leading to a reversal of the treatment effect over time.

When weighing the evidence from clinical trials for a treatment decision in an individual patient, physicians must

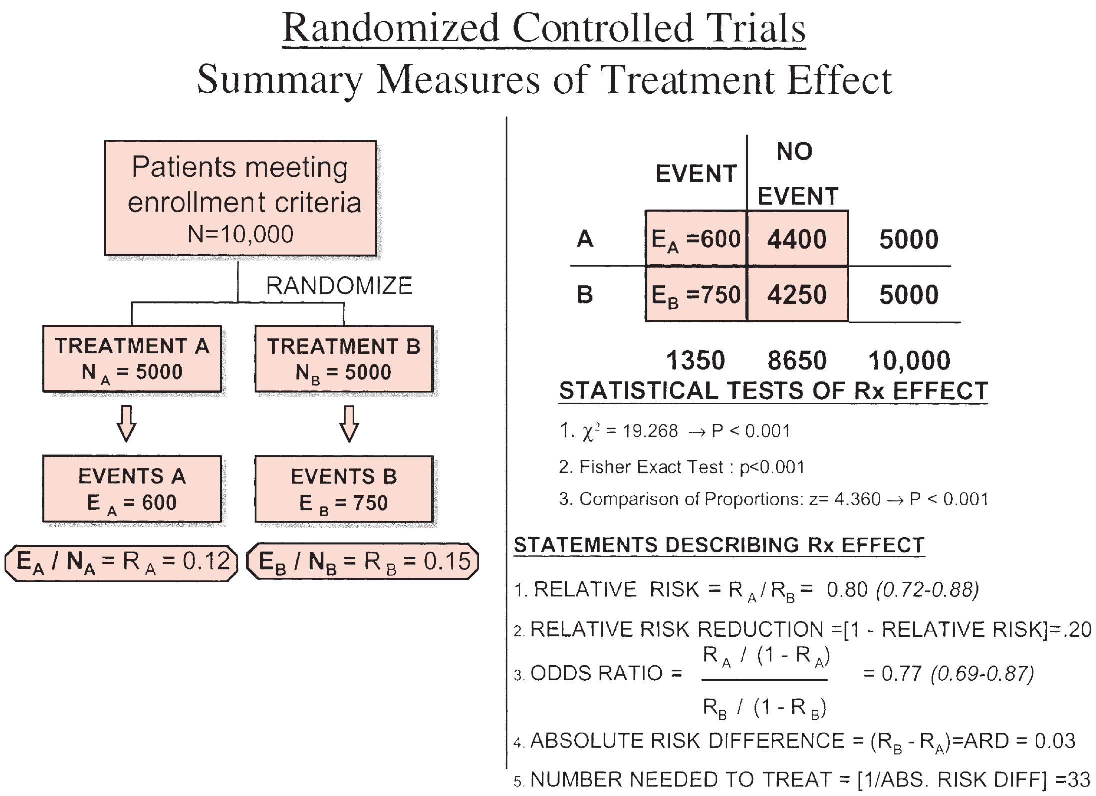

Figure 1–7 Evaluation of a clinical trial. In this example, 10,000 patients meeting enrollment criteria for the randomized controlled trial (RCT) are randomized such that 5000 patients receive treatment A and 5000 patients receive treatment B. Six hundred patients assigned to treatment A experience an event (e.g., death) yielding an event rate of 12%, compared with 750 patients assigned to treatment B, yielding an event rate of 15%. The 2 × 2 table (*right*) is then constructed, and various statistical tests are performed to evaluate the significance of the difference in event rates between group A and group B. Common statements describing the treatment effect are the relative risk (of events in treatment A versus treatment B); the odds ratio (for development of events in treatment A versus treatment B), or the absolute risk difference (of events in treatment A versus treatment B) using the formulas shown. A clinically useful method of expressing the results is to calculate the number of patients that need to be treated to prevent one event. (Adapted from Antman EM: Clinical trials in cardiovascular medicine. Circulation 2001;103:E101-4.

consider more than the level of significance of the findings.[73] In addition to the rationale for a given treatment, practitioners need to know which patients to treat, what drug and dose to use, and when and where therapy should be initiated. Not all clinical trial reports provide all information required to form a complete assessment of the validity, precision, and implications of the results and answers the questions noted previously.[74] In addition, clinicians are cautioned against overinterpreting subgroup analyses from RCTs. Most RCTs lack sufficient power to adequately assess treatment effects in multiple subgroups; repeated statistical testing across several subgroups can lead to false-positive findings by chance, and it is, therefore, preferable to present subgroup results in a graphic format depicting the point estimate and confidence intervals to illustrate the range of possible treatment effects.[75] In an attempt to introduce consistency in the reporting of clinical trials in the biomedical literature, a checklist of information for trialists, journal editors, peer-review panels, and the general medical audience was proposed (Table 1–5).[76] The presentation of a minimal set of uniform information in clinical trial reports should assist clinicians in making treatment decisions.[77]

Detection of Treatment Effects in Clinical Trials

The interplay of a variety of factors influences the ability of investigators to detect a treatment effect (benefit or harm) in a clinical trial (Fig. 1–8). Variables set by investigators during the design of a clinical trial include (1) the definition of events that constitute the trial endpoints (e.g., a hard endpoint such as death is infrequent, resulting in fewer events observed compared with a composite endpoint); (2) the duration of follow-up—short-term follow-up limits the time during which events may occur and reduces the likelihood of detecting harm; and (3) sample size—an inadequate sample size places investigators at the risk of a large type II error and failure to detect a treatment effect when one exists.[72]

Variables related to both the patient and the treatment being investigated influence the relative difference in events in the treatment groups and may minimize or magnify the signal of increased risk of events. These include: (1) the risk of events in the control group—the impact of the test treatment may be less evident in healthier subjects where relatively few events occur in the control group; (2) the relative risk of events in

Table 1–5 Checklist of Information for Inclusion in Reports of Clinical Trials

Introduction

A priori hypothesis, specific protocol objectives

Methods

Study As Designed Includes

- Planned study population, including controls
- Inclusion and exclusion criteria
- Planned subgroup analyses
- Prognostic factors that may affect study results
- Outcome measures and minimum difference(s) to be considered clinically important
- Planned treatment interventions
- Method of assignment of subjects to treatments (for example, randomization method, blinding or masking procedure, matching criteria)
- Planned sample size, power calculations
- Rules for stopping the study
- Methods of statistical analysis in sufficient detail to permit replication

Results

Study As Conducted Includes

- Inclusive dates of accrual of study population
- Sample size achieved
- How many subjects were excluded or withdrew and the reasons
- Demographics and clinical characteristics of the study population, including controls
- How the study as conducted deviated from the study as planned and the reasons (for example, compliance)

Study Findings Include

- Estimates of treatment effects, stated as comparisons among treatment groups (for example, differences in risks, rates, or means of outcome measures, as well as exact P values, not just $P < .05$)
- Measures of precision for outcome measures and for estimates of treatment effects (confidence intervals, standard errors)
- Summary data and appropriate descriptive statistics
- Complications of treatment
- Repository where original data can be obtained

Discussion

- Interpretation of study findings
- Results considered in the context of results in other trials reported in the literature

Modified from Working Group on Recommendations for Reporting of Clinical Trials in Biomedical Literature. Call for Comments on a Proposal to Improve Reporting of Clinical Trials in the Biomedical Literature. Ann Int Med 1994;121:894-95.

the treatment group—this is related both to the intrinsic properties of the treatment being investigated and the choice of the comparator arm (e.g., a treatment effect is more easily detected if the comparator arm is placebo and less readily detected in trials with an active comparator); (3) and interactions with other treatments. If the test treatment improves symptoms or biomarker measurements relative to control, the control group may be exposed to more counterbalancing beneficial therapies, a phenomenon described as intensification. Although this cannot be prevented ethically, consideration of this issue in trial design and monitoring during the study can minimize the impact of intensification.

To complicate the situation further, the interface of the patient and the treatment may change over the course of exposure to the treatment. For example, development of diabetes or worsening hypertension may culminate in disruption of a high risk or vulnerable plaque with the development of a superimposed thrombus. As the acute situation evolves, the risk in the control arm may change and the relative risk associated with a drug may also change—both in an adverse direction.

These considerations assume particular importance when assessing whether a signal of harm is present with a given treatment (e.g., the cardiovascular risks associated with coxib use).[72] One may depict the relation among the risk of events in the control group (control event rate, CER), the relative risk of events with a particular drug (RR), and the NNH (critically related to the ability to detect a signal of harm), related to each other by the formula: $NNH = 1/ [(RR - 1) \cdot CER]$. The surface shown in Figure 1–9 rises steeply to a high NNH (difficulty in detecting harm) with a low rate of events in the control group and/or low relative risk in the treatment group. The ability to detect harm improves as NNH drops with increasing rates in the control arm and/or increasing relative risk in the treatment arm (see Figs. 1–8 and 1–9).

When administering therapies that have a beneficial effect but are associated with serious potential for harm, the general goal is to operate on the steep portion of the surface in Figure 1–9, thereby minimizing patient risk. This can be accomplished by preferentially prescribing treatments (e.g., coxibs) only to patients at low risk of events (i.e., moving to lower rates of events in the control group in Fig. 1–9). Selecting drugs with a lower risk of harmful events and minimizing the dose and duration of treatment are also advisable (i.e., moving to a lower relative risk in Fig. 1–9).

META-ANALYSIS

Frequently, clinicians are faced with many trials of a given treatment, some of which provide seemingly conflicting results. A method of summarizing the data is needed. *Meta-analysis* is a systematic, quantitative synthesis of data from multiple clinical sources that address a related question. Meta-analysis is a well-defined, scientific statistical discipline with established methods and standards. Synonymous terms encountered in the literature include *overview*, *pooling*, *data pooling*, *literature synthesis*, *research synthesis*, and *quantitative review*. Although the concept of data pooling has existed since the early 1900s, its introduction into clinical literature has met with mixed reactions, ranging from exuberant support and in-depth analysis to overt skepticism. The large number of meta-analyses published in the field of cardiovascular medicine suggests that the technique is gaining in popularity and is likely to play an important role in the complex process of therapeutic decision-making in the future, as well as in regulatory approval of new drugs and devices used in cardiology.[78-82] Authoritative bodies have begun to establish

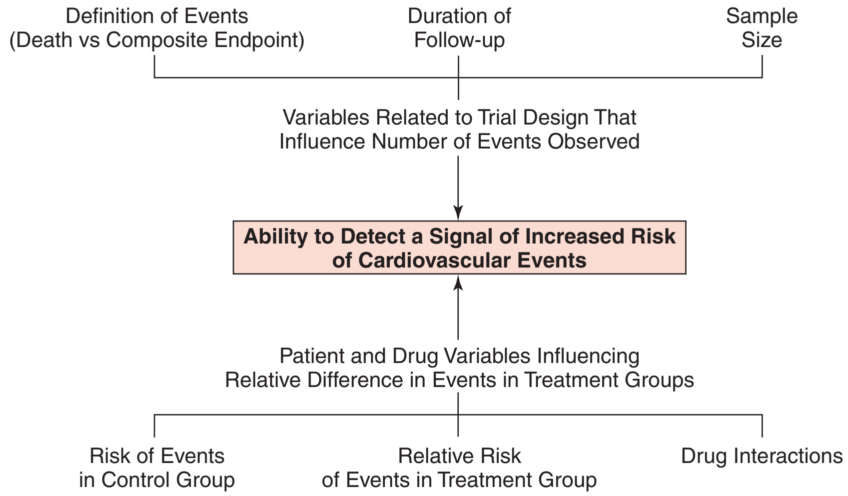

Figure 1–8 Detection of treatment effects in clinical trials. Factors related to trial design (*top*) and to the patient and drug being investigated (*bottom*) are shown. The interplay of these factors influences the ability to detect a treatment effect in a clinical trial. (Redrawn from Antman EM, DeMets D, Loscalzo J: Cyclooxygenase inhibition and cardiovascular risk. Circulation 2005;112:759-70.)

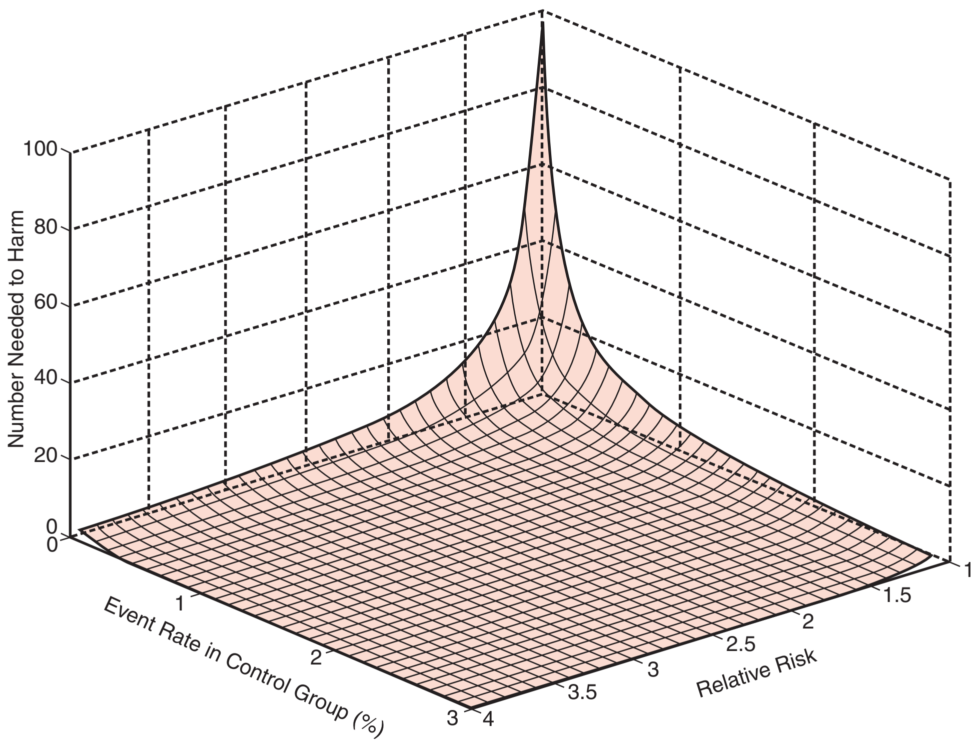

Figure 1–9 The relation of the event rate in the control group and relative risk of cardiovascular events with the treatment being investigated determines the number of patients who need to be treated with the drug to observe one cardiovascular event (Number Needed to Harm). The surface generated can be used to understand the relative ease or difficulty of detecting a signal of harm with a particular treatment (e.g., coxibs). (Redrawn with permission from Antman EM, DeMets D, Loscalzo J: Cyclooxygenase inhibition and cardiovascular risk. Circulation 2005;112:759-70.)

standards for improving the quality of reports of meta-analyses of clinical trials (QUOROM = *QU*ality *O*f Reporting *O*f *M*eta-analyses),[83] and observational studies (MOOSE = *M*eta-analysis *O*f *O*bservational Studies in Epidemiology).[82] Meta-analysis software is available both commercially and on several public domain Web sites.[84]

When pooling studies, it is important that all available trials are located and considered for inclusion. Because investigators are more likely to report only positive findings, the issue of publication bias must be considered when searching for trials to include in a meta-analysis.[85] Statistical techniques have been proposed to screen for publication bias, although this appears to be more of a concern for observational and laboratory-based experimental studies than for RCTs.[86]

The fundamental principle of a meta-analysis is that the statistical power to estimate a treatment effect is enhanced because of an increase in sample size. An inherent assumption is that the available studies are sufficiently similar that pooling is appropriate. The various techniques of pooling construct a weighted average of the study outcomes; the selection of weighting techniques and the approach to handling between-study variability distinguish the different analytic methodologies.[87] Some authorities have proposed incorporating an adjustment for variations in the quality of individual trials when performing a meta-analysis, but this requires further research before formal recommendations can be made.[88]

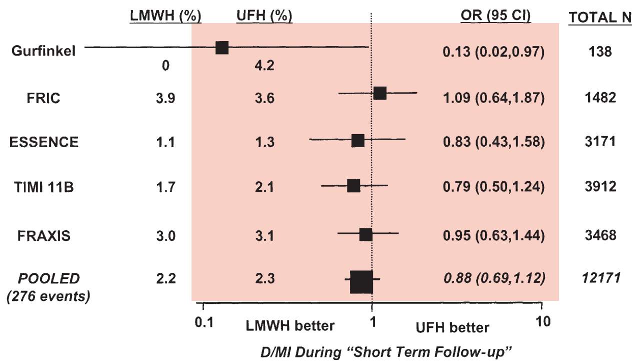
Another important dimension of meta-analysis is the composite overview of therapies considered to be in the same "class." Particularly in the formulation of clinical practice guidelines, the general policy has been to review data for all members of the same class, and then to make a

recommendation about the class rather than individual compounds or devices. In cardiovascular therapeutics, controversy has arisen concerning the antiplatelet agent, statin, low molecular weight heparin, and β-blocker classes and whether the risks and benefits of the many available agents are similar for them to be "lumped together."[89]

The low-molecular-weight heparins provide an excellent example of the difficulty involved in this issue. By lumping together all members of the class, the American College of Cardiology/American Heart Association Guidelines Committee on the Management of Patients with Unstable Angina was able to make a statement that low-molecular-weight heparins are superior to no antithrombin therapy.[89] However, when low-molecular-weight heparins are compared with unfractionated heparin, if all trials are pooled, there is no clear advantage for low-molecular-weight heparins compared with unfractionated heparin (Fig. 1–10A).[90] However, when data for the low-molecular-weight heparin enoxaparin are separated from the remaining data, enoxaparin is seen to be significantly superior to unfractionated heparin (see Fig. 1–10B).[89,90] Although testing for heterogeneity is a quantitative tool to guide investigators as to the advisability of "lumping" versus "splitting," the test is not powerful, and additional tools are needed to sort out the development of quantitative estimates about class effect versus the attributes of individual therapies.

Principles of Pooling Studies

The *fixed-effects model* (Fig. 1–11) assumes that the trials are sampled from a homogeneous group. Under the homogeneity assumption, each trial provides an estimate of the single true treatment effect, and differences between the estimates from the various trials are the result only of experimental error (*within-trial variability*). The *random-effects model* assumes that the trials are heterogeneous and that differences among the various estimates of the treatment effect are due to both experimental error (*within-trial variability*) and differences among the trials, such as trial design and characteristics of the patients enrolled (*between-trial variability*). The random-effects model is generally favored because heterogeneity that cannot be explained by experimental error often exists among trials, and this model takes such heterogeneity into account in estimation and hypothesis testing.[91] Unless extreme heterogeneity is present among the trials, the point estimate of the treatment effect is similar using fixed- and random-effects



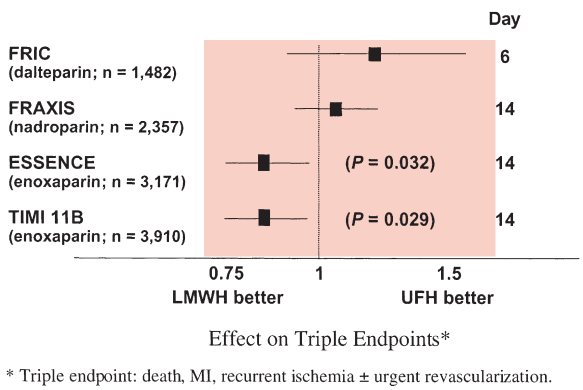


Figure 1–10 Examples of the complexity of pooling studies of multiple drugs within a class. Several different low-molecular-weight heparin (LMWH) preparations have been studied in patients with unstable angina/non ST-segment elevation myocardial infarction (MI). Although there is general agreement that LMWHs are superior to placebo for reducing death and cardiac ischemia events, controversy exists when LMWHs are compared with unfractionated heparin (UFH). **A,** Results of five trials of three different LMWHs versus UFH are plotted individually and then pooled under the assumption that they exhibit a class effect with little heterogeneity among the findings of the various trials. The pooled analysis shows a point estimate favoring LMWH for reducing death/MI during short-term follow-up, although the confidence intervals are wide (owing to the low rate of events that occurred among the 12,171 patients at the time of ascertainment of the endpoint) and overlap unity, and the authors concluded there was no evidence of the superiority of LMWHs over UFH. **B,** The four large phase III trials of three different LMWHs are plotted individually. Note that the endpoint analyzed is a composite of death/MI/recurrent ischemia ± urgent revascularization and is ascertained at a later time point (6 to 14 days) than in **A**—two modifications that increase the power of the meta-analysis to discern differences among the LMWHs. Given the biochemical differences among the LMWHs and subtle but potentially important differences in trial design, the results were not pooled into a composite statement of LMWHs versus UFH. Two trials with enoxaparin show it to be significantly superior to UFH, whereas such a finding is not seen in the trials of dalteparin or nadroparin. ESSENCE, Efficacy and Safety of Subcutaneous Enoxaparin in Unstable Angina and Non-Q-Wave MI; FRAXIS, Fraxiparine in Ischemic Syndrome; FRIC, FRagmin In unstable Coronary artery disease; OR, odds ratio; TIMI, Thrombolysis In Myocardial Infarction. (Adapted from Eikelboom JW, Anand SS, Malmberg K, et al: Unfractionated heparin and low-molecular-weight heparin in acute coronary syndrome without ST elevation: A meta-analysis. Lancet 2000;355:1936-42 and Braunwald E, Antman EM, Beasley JW, et al: ACC/AHA guidelines for the management of patients with unstable angina and non-ST-segment elevation myocardial infarction. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee on the Management of Patients with Unstable Angina]. J Am Coll Cardiol 2000;36:970-1062.)

models, but the 95% CIs are generally wider with the random-effects method because they incorporate the uncertainty present in the among-trial variation (see Fig. 1–11).[21]

Cumulative Meta-analysis

Some analysts have incorporated a Bayesian approach to synthesis of the results of RCTs.[92] In an effort to shorten the time delay between the identification of an effective or ineffective therapy in clinical trials and translation of the findings into clinical practice, a related technique of continuously updating meta-analyses has been developed. This methodology, referred to as *cumulative meta-analysis*, updates the pooled estimate of the treatment effect each time the results of a new trial are published (Figs. 1–12 and 1–13).

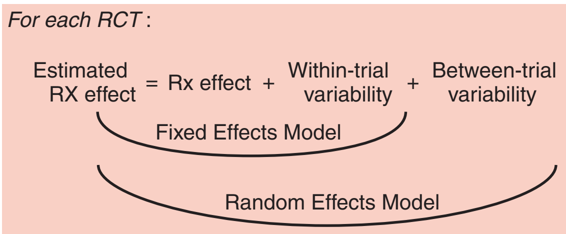

Figure 1–11 Fixed-effects and random-effects models for pooling results of randomized clinical trials (RCTs) in a meta-analysis. The fixed-effects model assumes that the trials are homogeneous and differences between their estimates of the true treatment (Rx) effect are due only to experimental error (within-trial variability). The random-effects model assumes that the trials are heterogeneous and that differences between estimates of the treatment effect are due to experimental error (within-trial variability) and differences among the trials (between-trial variability).

Cumulative meta-analysis is rooted in a Bayesian framework, because it provides the history of the evolution of the posterior probability distribution of clinical trial results and allows one to quantify changes in beliefs about treatment effects as the data accumulate.[141] When cumulative meta-analyses on RCTs of therapies for acute and secondary MI were compared with the textbook chapters and review articles, discrepancies were detected between the meta-analytic patterns of effectiveness and the recommendations of clinical experts.[93] The reasons for these discrepancies may be complex and include a limited ability of authors of review articles to keep abreast of all the RCTs in a particular area; failure to recognize the limited power of small "negative" trials; unfamiliarity or uncertainty about meta-analyses; and a natural conservatism about recommending new therapies until extensive, large-scale clinical trials are completed. The use of cumulative meta-analysis in formulating therapeutic guidelines in the future requires additional methodological study before its role can be properly defined. *Simulation studies* suggest that there may be considerable sampling variation in the time when a cumulative meta-analysis is first significant.[94] Simulation methods can also estimate the type I error and power of a meta-analysis.[94] Because of the possibility in

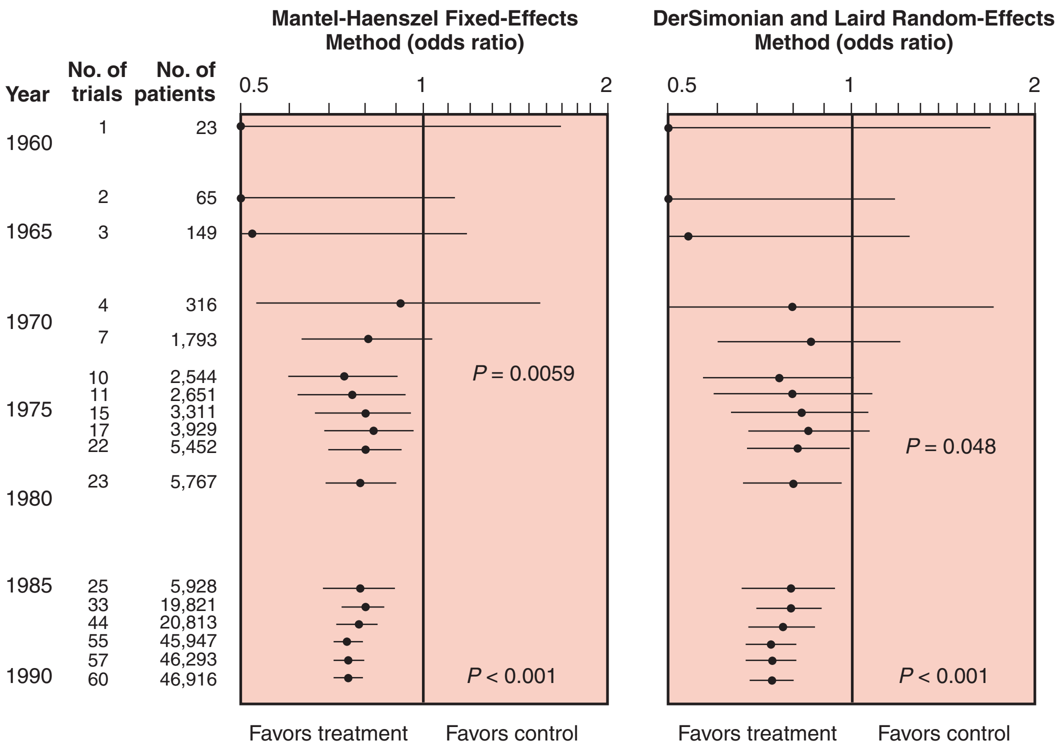

Figure 1–12 Cumulative meta-analyses of 60 trials of intravenous thrombolytic agents for myocardial infarction by the Mantel-Haenszel fixed-effects method and DerSimonian and Laird random-effects method. The odds ratios and 95% CIs for a treatment effect on mortality are shown on a logarithmic scale. The statistical significance reached less than 0.05 in 1973 with the fixed-effects method and in 1977 with the random-effects method. (Redrawn from Lau J, Antman EM, Jimenez-Silva J, et al: Cumulative meta-analysis of therapeutic trials for myocardial infarction. N Engl J Med 1992;327:248-54.)

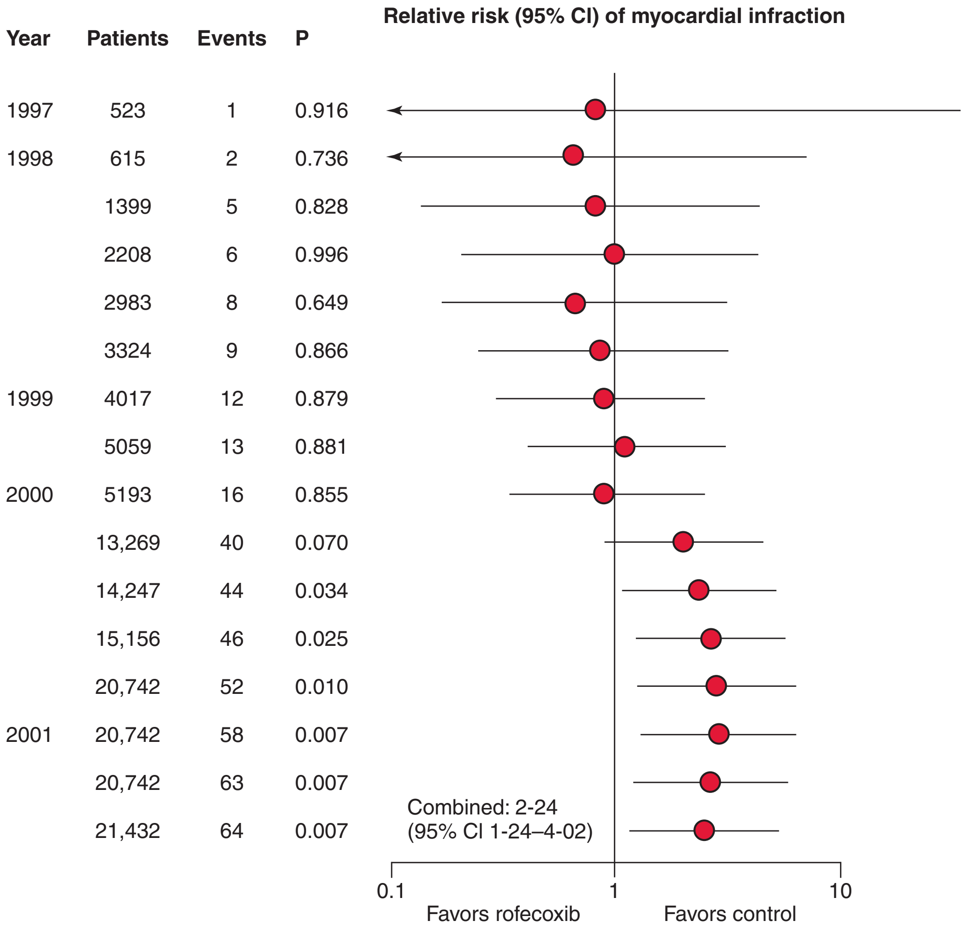

Figure 1–13 Cumulative meta-analysis of 16 randomized clinical trials (RCTs) comparing rofecoxib versus control. An increased risk of myocardial infarction was already evident in 2000 when 14,247 patients had been randomized and a total of 44 events had occurred. Subsequent trials increased the number of patients to 21,432 and the number of events to 64. The confidence intervals were narrowed as subsequent trials were reported but the point estimate still favored control therapy. (Redrawn with permission from Juni P, Nartey L, Reichenbach S, et al: Risk of cardiovascular events and rofecoxib: Cumulative meta-analysis. Lancet 2004;364: 2021-29.)

certain collections of trials of increasing risks of type I error when multiple looks are taken at the accumulating data, more stringent statistical standards for the declaration of significance may be required. One proposal that has been introduced to deal with cumulative meta-analysis is the concept of *optimum information size*, which is defined as the minimum amount of information required in the collective literature to arrive at a reliable conclusion regarding an intervention.[95] Using estimates of event rates and anticipated treatment effects, standard sample size calculations for a randomized trial may be used to determine the cumulative number of patients that must be enrolled in a series of trials to provide the optimum information size. The same interim monitoring techniques used by a DSMB for an individual RCT can be adapted to monitoring evidence as trials are added to a cumulative meta-analysis.[143]

Meta-regression

The majority of meta-analyses in the cardiovascular literature report an average treatment effect estimated from the available studies. To move beyond the current methodology, several investigators have proposed that estimates of the treatment effect be expressed as a function of study-specific features such as years of study, drug dose, characteristics of patients enrolled (e.g., age, gender, race), or average mortality in the control group.[96,97] Adjustments for covariates in clinical trials can be accomplished with the use of regression techniques, and thus the term *meta-regression* has been introduced.[98] Meta-regression is useful for identifying sources of heterogeneity among clinical trials and for establishing clinically important relationships such as dose-response and changes in the incidence of outcome variables (e.g., primary ventricular fibrillation in acute MI) between studies conducted in the distant past and those conducted later.[150]

Future Trends in Meta-analysis

The previous discussion on meta-analysis treats the individual RCT as the unit of analysis. The difference between the aggregate result for the test and control groups for each trial is calculated and then pooled with the observed differences in other trials. Ideally, the individual patients in each trial should be the *unit of analysis* to assess whether the treatment effect is modified by certain patient characteristics. Collaborative efforts of trialists studying antiplatelet therapy for a wide range of cardiovascular conditions, fibrinolytic therapy for suspected MI, and coronary artery bypass surgery (CABG) versus medical therapy for coronary heart disease illustrate the power of pooling individual patient level data to provide estimates of the treatment effect stratified by various clinical profiles (e.g., age, gender, ventricular function, history of infarction or stroke)[78,79,99] (Figs. 1–14 and 1–15). The success of these efforts is likely to inspire other investigators to plan prospectively for pooling of case reports from information across related trials.

Presentation features	Percent of patients dead: Fibrinolytic	Percent of patients dead: Control	Stratified statistics: O–E	Stratified statistics: Variance	Chi-square test of odds ratios in different patient categories: Heterogeneity	Trend

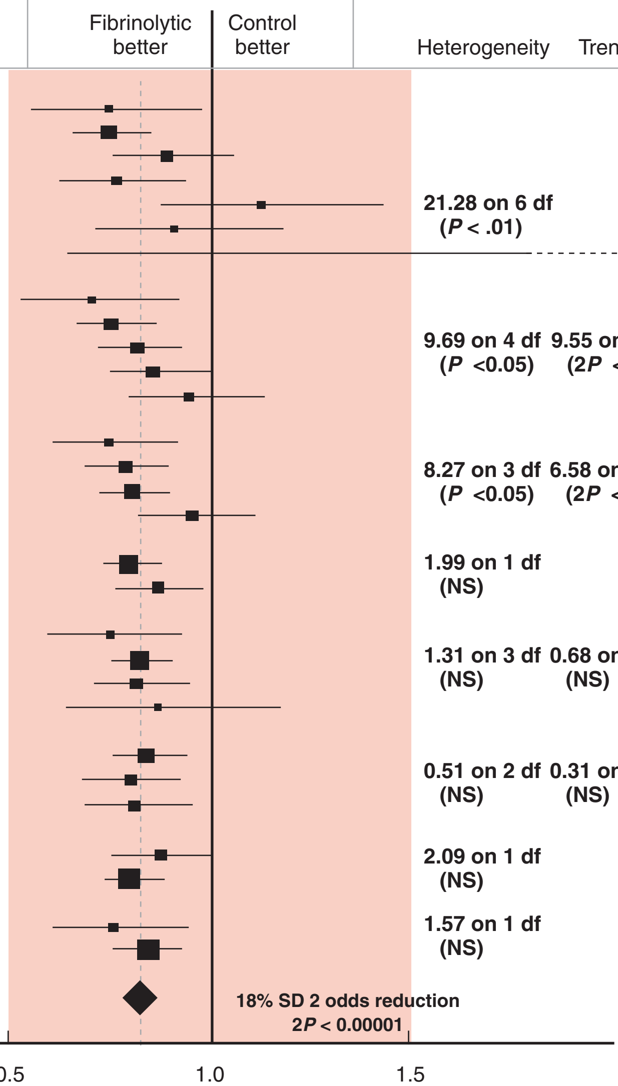

Figure 1–14 Proportional effects of fibrinolytic therapy on mortality during days 0 to 35 subdivided by presentation features. "Observed minus expected" (O-E) number of events among fibrinolytic-allocated patients (and its variance) is given for subdivisions of presentation features, stratified by trial. This is used to calculate odds ratios (ORs) of death among patients allocated to fibrinolytic therapy to those among those allocated control. ORs (filled squares with areas proportional to amount of "statistical information" contributed by the trials) are plotted with their 99% confidence intervals (CIs) (*horizontal lines*). *Squares to left of the solid vertical line*, Benefit (significant at two-tailed $P < 0.01$ only where entire CI is to left of vertical line). Overall result and 95% CI (*represented by diamond*) with overall proportional reduction in the odds of death and statistical significance given alongside. The χ^2 tests for evidence of heterogeneity of, or trends in, the size of ORs in subdivisions of each presentation feature are also given. BP, blood pressure; ECG, electrocardiogram; MI, myocardial infarction. (Redrawn from Fibrinolytic Therapy Trialists' [FTT] Collaborative Group: Indications for fibrinolytic therapy. Lancet 1994;343:311-22.)

How to Read and Interpret a Meta-analysis

A series of practical questions that readers should ask when assessing a meta-analysis are shown in Table 1–6. The same standards should apply whether the physician is reading an overview of a therapeutic modality or the results of a diagnostic test for a medical condition.[100,101] Readers must be convinced that the authors attempted to answer a focused question of clinical importance, that all relevant studies were included, and that an attempt was made to assess the data for evidence of heterogeneity and to explain between-trial variability if it is present. As with individual clinical trial reports, an overview should include a statement of the pooled treatment effect that incorporates both RR reduction and ARD and conveys the information in a clinically practical fashion (e.g., number to treat and number of lives saved per 1000 patients treated).

When attempting to apply the findings of an RCT or overview of multiple RCTs to an individual patient, the clinician

Category of trial	No of trials with data	No (%) of vascular events: Allocated antiplatelet	Adjusted control	Observed-expected	Variance	% Odds reduction (SE)
Previous myocardial infarction	12	1345/9984 (13.5)	1708/10,022 (17.0)	−159.8	567.6	25 (4)
Acute myocardial infarction	15	1007/9658 (10.4)	1370/9644 (14.2)	−181.5	519.2	30 (4)
Previous stroke/transient ischemic attack	21	2045/11,493 (17.8)	2464/11,527 (21.4)	−152.1	625.8	22 (4)

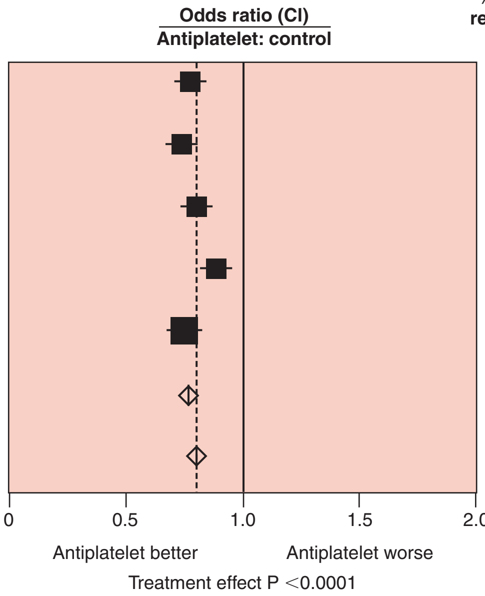
Other high risk	140	1638/20,359 (8.0)	2102/20,543 (10.2)	−222.3	737.0	26 (3)
Subtotal: all except acute stroke	188	6035/51,494 (11.7)	7644/51,736 (14.8)	−715.7	2449.6	25 (2)
All trials	**195**	**7705/71,912 (10.7)**	**9502/72,139 (13.2)**	**−810.3**	**3244.9**	**22 (2)**



Heterogeneity of odds reductions between:
5 categories of trial: χ^2=21.4, df=4; P=0.0003
Acute stroke v other: χ^2=18.0, df=1; P=0.00002

Figure 1–15 Proportional effects of antiplatelet therapy on vascular events (myocardial infarction, stroke, or vascular death) in five main high-risk categories. Stratified ratio of odds of an event in treatment groups to that in control groups is plotted for each group of trials (*black square*) along with its 99% CI (*horizontal line*). Meta-analysis of results for all trials (and 95% CI) is represented by an *open diamond*. Adjusted control totals have been calculated after converting any unevenly randomized trials to even ones by counting control groups more than once, but other statistical calculations are based on actual numbers from individual trials. (Redrawn with permission from Antithrombotic Trialist's Collaboration. Collaborative meta-analysis of randomised trials of antiplatelet therapy for prevention of death, myocardial infarction, and stroke in high risk patients. BMJ 2002;324:71-86.)

must determine whether his or her patient is similar to those enrolled in the trials.[102-104] Although there may be a temptation to focus on subgroup information from the meta-analysis to determine whether a given patient is likely to experience more or less than the average benefit of the treatment, this must be done cautiously.[74] Subgroup analyses are more reliable if there is a highly significant treatment difference, if they represent hypotheses established before trial initiation, if they are consistent across studies, and if they are biologically plausible.[100] The potential risks of the therapeutic intervention should be considered and discussed with the patient to ensure that the treatment decision is consistent with his or her concerns about quality of life.

COST-EFFECTIVENESS ANALYSIS

Cost and *resource allocation* are priorities in the health care agenda of physicians, as well as health care planners, administrators, and economists. Techniques for examining costs in relation to benefit or effectiveness of medical interventions are, therefore, of great importance—especially in the practice of cardiology.[105,106]

Cost-effectiveness analysis (CEA) is the standard for examining cost in relation to benefit. Here, the total cost (*resource impact*) of a treatment in dollars is determined in relation to its effectiveness to determine the "value" of the service. Effectiveness may be expressed in terms of *years of life saved* (YLS) or prolonged, where it is called *CEA*. *Quality-adjusted life years* (QALY) prolonged are also generally called CEA but may be called *cost utility analysis;* or they may be given in terms of the monetary value of life, where the technique is labeled *cost benefit analysis*.[107,108]

As generally applied in CEA, the cost and *life expectancy* (LE) or QALY for one strategy are compared with those of another "competing" strategy. For example, in comparing CABG surgery with medical therapy, one determines the entire cost (including follow-up and future events) and the LE of surgery and then subtracts the cost and the LE of drug therapy.

$$\frac{\Delta\ \text{Cost}}{\Delta\ \text{YLS}} = \frac{\text{Cost}_{\text{CABG}} - \text{Cost}_{\text{med Rx}}}{\text{LE}_{\text{CABG}} - \text{LE}_{\text{med Rx}}}$$

In this way, the *incremental* or *marginal* cost effectiveness (i.e., added cost for added benefit) can be derived.

CEA can be applied to any diagnostic or treatment strategy (although for diagnostic strategies, CEA must take into account resulting treatments as well). At times, only the cost and not the effectiveness (and thus not the "value") of a medical service is determined. This technique is called *cost identification* or *cost minimization analysis*.[107,109]

The usefulness of CEA depends on the ability to compare among health care interventions.[107-111] This may be accomplished by league tables (essentially a rank order list of the cost-effectiveness of a number of medical interventions) or other means (see later). Some authors have introduced a note of skepticism regarding CEA reports because those funded by for-profit organizations are more likely to describe favorable findings with attractive QALY calculations.[112,113]

Components of Cost-Effectiveness Analysis

Cost

Cost determination is complex, and there has been less than perfect consistency among analyses, which can be greatly influenced by the cost accounting method used.[97-111,114] *Actual cost* is defined as the value of services incurred by the provider of care. Charges are "prices" for services. Payments are the monies paid to providers for services.

Actual costs are divided into *direct* and *indirect costs*. Direct costs are the direct organizing and operating expenditures in the delivery of care, and they may be medical (e.g., provider services, hospitalization, drugs, devices, and so on) or nonmedical (e.g., food, transportation, and housekeeping).[115,116] *Indirect* cost in health economic parlance may refer to one of two concepts. In hospital parlance, indirect costs refer to *overhead* costs such as for food, mortgage, and so on, and are roughly equivalent to *direct, nonmedical costs*. In other parlance, indirect costs refer to those resulting from loss of income due to illness or death (labor and productivity issues) and can be prodigious for heart disease.[107-111,114,115]

Pain, grief, and suffering related to illness are called *intangible costs*. Although included in CEAs, intangible costs may be part of the denominator in cost-benefit analysis (see later).[117] *Fixed costs* do not vary within a certain time period, usually 1 year (e.g., mortgages, depreciation, and so on). *Variable costs* are those directly applied to services (e.g., laboratory tests, nursing, billing, surgical supplies).[116]

Average (or *unit*) *costs* are total costs divided by total units, whereas *incremental costs* are those incurred by adding one additional unit of service, such as a program or an option. For example, the hospital costs for 1000 cardiac catheterizations may be $1.5 million or $1,500 *average* per case. If the capacity is high and the schedule has openings, the incremental cost of adding 50 *elective* catheterizations might be relatively little—mainly the cost of supplies. On the other hand, in a full schedule, the incremental cost for elective catheterization would involve overtime payments and other extra operating costs.

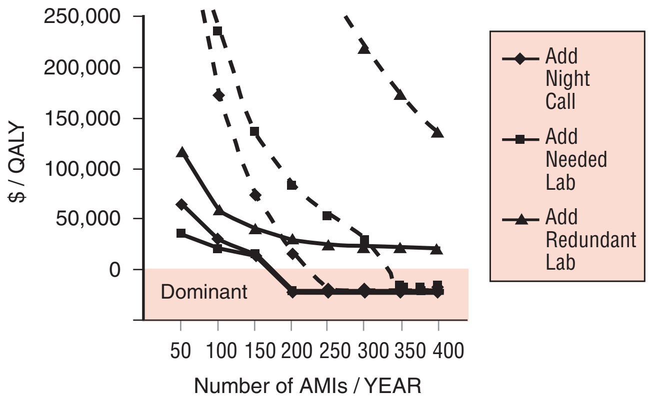

Figure 1–16 Costs/quality-adjusted life year (QALY) of primary percutaneous transluminal coronary angioplasty (PTCA) versus thrombolysis in acute myocardial infarction (AMI), demonstrating the effect of adding emergency hospital services, hospital volume, and differences with the use of randomized clinical trials (RCTs) (efficacy) versus community-based observational (effectiveness) data assumptions. *Horizontal axis*, number of AMIs per year at the admitting hospital (volume); *vertical axis*, cost effectiveness ($/QALY). In the base case in this analysis, the hospital had 200 discharges for AMIs; an existing cardiac catheterization laboratory that performed elective procedures during weekdays; surgical backup; two technical staff members on night call; primary angioplasty offered 24 hours a day/7 days a week; and RCTs were used to derive outcomes (efficacy). *Solid lines*, cost/QALY with "efficacy" assumptions derived from RCTs; *dashed lines*, results estimated from community-based observation data ("effectiveness"). At base case, primary PTCA is dominant. *Diamonds*, results of adding night call; *squares*, added needed laboratory (for both elective and primary PTCAs); *triangles*, added redundant laboratory (for primary PTCA only). Note that with any assumptions, the incremental costs of services can be great, especially where hospital volume is small. Regarding use of RCT or community data (*solid versus dashed lines*), there was little impact on the addition of needed laboratory or night call with high hospital volume (primary PTCA is dominant in both instances), but as AMI volume moves below 200 per year, the impact is much more profound. (Adapted from Lieu TA, Gurly RJ, Lundstrom RJ, et al: Projected cost-effectiveness of primary angioplasty for acute myocardial infarction [with update to 1997 dollars and assumptions regarding dominance maintained]. J Am Coll Cardiol 1997;30:1741-50.)

The impact on cost effectiveness of adding capacity for service is shown in Figure 1–16. Cost per QALY is plotted against the number of baseline acute MIs per year in a particular hospital. The capacity to perform primary percutaneous transluminal coronary angioplasty (PTCA) requires night call

and the potential for a rapid phase-in of a "needed" or "redundant" extra cardiac catheterization laboratory.[118] The incremental cost for adding these additional services is reflected in the less favorable cost per QALY, which rises markedly as the annual acute MI volume falls. Figure 1–16 also compares use of RCT with community-based observational data (see later).

The above distinctions are important in analyzing cost-cutting measures. For example, a decision not to perform a procedure would realize a much lower cost savings in the setting of unused capacity than if one had to add personnel or open up a new procedure room. In Figure 1–15, the markedly less favorable cost effectiveness of emergency primary angioplasty with lower hospital volume has implications for determining which hospitals can efficiently offer this service and for regionalization of services.[119] Such direct policy implications on resource allocation can give CEA political overtones in many situations.

Charges and Payments

The use of charges represents a simplified approach.[120] Charges for physician services in the United States are set well above any reimbursement level so as to assure reimbursement at all levels of payment. In CEAs, it has been common to determine charges and then derive costs based on cost/charge ratios using the Medicare Cost Report. Payments (e.g., Medicare reimbursements) have also been used in analyses.[121]

Resource Consumption

The two steps in determining the overall costs of a medical intervention are to determine the cost of each item (*unit*) and how often each item (unit) is used (*resource consumption*). This includes recurring events such as routine tests, visits, hospitalizations, and others. For example, resource consumption for an implantable cardioverter-defibrillator would include the initial hospitalization, the number of visits required for diagnostic testing, frequency of exercise and other tests, laboratory tests, and the risk of complications and consequent interventions.[122] The cost of each item would then be multiplied by the number thus derived to arrive at overall cost. Resource consumption data are derived from RCTs and data bases[122-125] when possible, but often expert opinion[126,127] is used.

Effectiveness

The most direct index of effectiveness is prolongation of life, expressed as YLS. Some analyses have used the number of lives saved.[128] In addition, because combined endpoints are frequently used in RCTs, cost per *event-free year* has been[129] applied. LE data may come from individual RCTs, meta-analyses of trials, or historical and case-control studies.[123,130-133] RCTs provide only relatively short-term data for LE, generally 2 to 5 years (although some RCTs now have longer term data, e.g., 10 to 12 years,[134] whereas the time horizons of CEAs are usually lifetime. To complete this time horizon, one must merge treatment efficacy coefficients from randomized trials or data bases with natural history studies (the Framingham trial is frequently used),[135] population-based life tables and U.S. Vital Statistics—methodology that addresses different population sets for each component.

Figure 1–17 illustrates the effect of changing the duration of benefit on the results of CEA. Here an analysis was performed on 6 RCTs of prophylactic implantation of the implantable cardioverter-defibrillator (ICD) in which the device was found to prolong life. The horizontal axis is time of benefit and the vertical axis is cost/QALY. In Figure 1–17A, it was assumed that the ICD conferred no additional benefit after the specified time on the horizontal axis; lifetime costs were included and survival curves were assumed to be parallel after the time period. In Figure 1–17B, it was assumed that neither costs nor benefits were incurred after the specified time period. Note the degree of improvement in cost-effectiveness as the time of benefit increases in duration as well as overall differences in results for the two approaches.[136]

The other major measure of effectiveness, the QALY, used in the denominator of CEA attempts to merge LE and health-related quality of life (HRQL). Specifically, the QALY is a downward adjustment in the value of a healthy year as a result of poor health factors (pain, disability, and so on) in the eyes of the patient. It is LE multiplied by a fraction, termed the *utility*, or *quality adjustment coefficient*, which represents the decline in quality of life caused by less-than-perfect health. For example, in a study of CABG surgery, the utility of angina pectoris was considered to be 0.7 with severe angina and 0.9 with mild angina.[137] These utility numbers are multiplied by LE to arrive at the QALY

$$\text{QALY} = \text{U} \cdot \text{LE}$$

where QALY is quality-adjusted life year, U is utility (in each health state), and LE is LE in years (from each health state). Therefore, 1 year of life rated as 70% of perfect health (U = 0.7) would have a QALY of 0.7, and 2 years would have a QALY of 1.4. This value is then put into the following formula:

$$\frac{\Delta\ \text{Cost}}{\Delta\ \text{QALY}} = \frac{\text{Cost}_{\text{new Rx}} - \text{Cost}_{\text{competing Rx}}}{\text{QALY}_{\text{new Rx}} - \text{QALY}_{\text{competing Rx}}}$$

A favored method of obtaining utilities is the *time tradeoff*.[138-141] An individual is asked what LE in perfect health would be equivalent to a longer LE with a health problem. If the individual considers that 1 year living with a given degree of angina is equivalent to 9 months in perfect health, then the utility is 0.75; for 8 months, it is 0.6, and for 6 months, it is 0.50. States felt to be worse than death have also been addressed.[142] *Standard gamble* assesses what one would gamble for a given beneficial option. For example, what mortality risk might one accept in CABG surgery for its benefit?[143] (Fig. 1–18). In other instances, short-term quality-of-life adjustments are made for transient incapacitation by a subtraction method (e.g., the amount of time in the hospital for a stroke might be subtracted from a "healthy year"). QALYs may be expressed as patient or community preference.[115-117]

An important issue no matter how QALYs are evaluated is their fundamentally subjective nature. For example, the subjective worth of a specific health state might be rated differently by individuals at different times. It might vary based on many other factors such as whether the anticipated state is one involving health improvement or decline, and the exact prognosis without treatment. One may also view things differently when asked hypothetically about a life-prolonging treatment

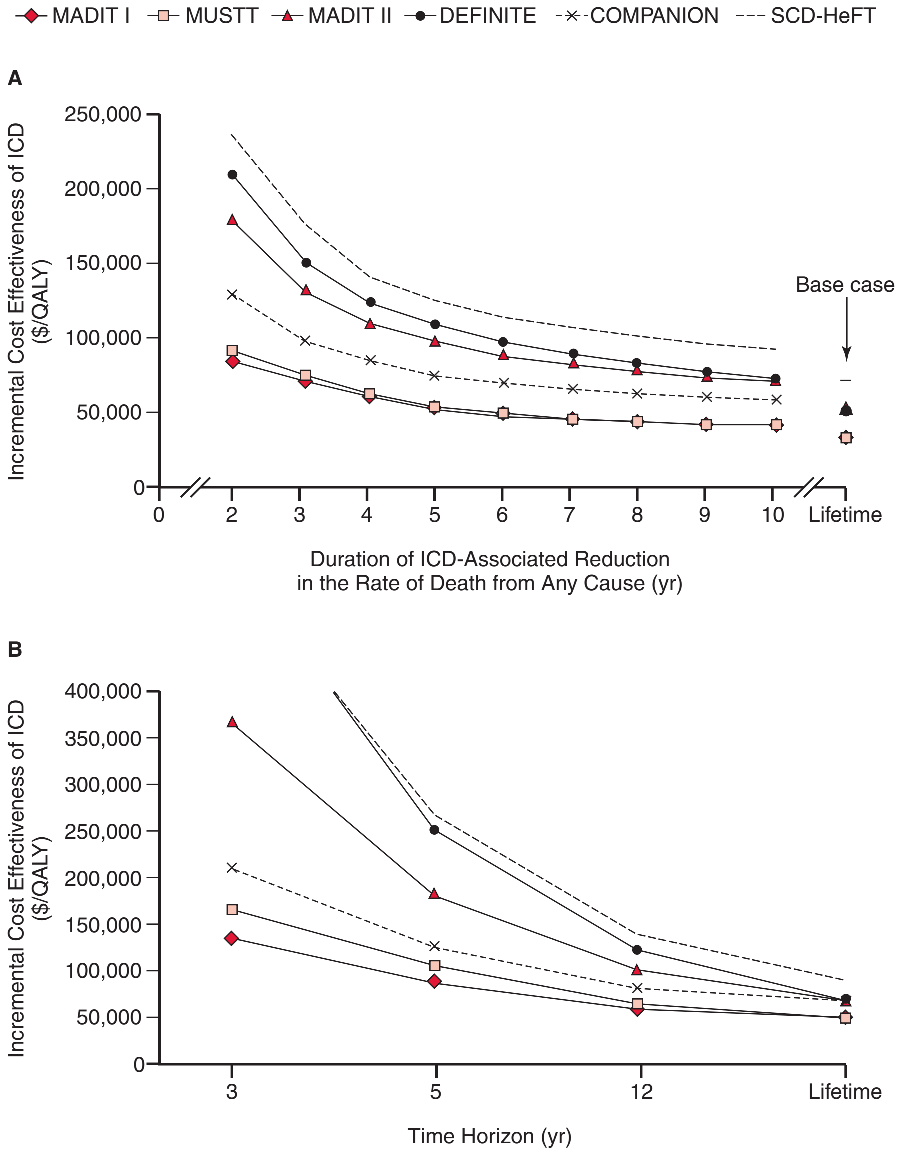

Figure 1–17 Variation in the incremental cost effectiveness of prophylactic implantation of an implantable cardioverter defibrillator (ICD) with changes in the time horizon of ICD effectiveness in preventing sudden death. Shown are results from six trials in which the ICD was found to be efficacious (Multicenter Automatic Defibrillator Implantation Trial I [MADIT I]; MADIT II; the Defibrillators in Non-Ischemic Cardiomyopathy Treatment Evaluation [DEFINITE] trial; the Comparison of Medical Therapy, Pacing, and Defibrillation in Heart Failure [COMPANION] trial; the Multicenter Unsustained Tachycardia Trial [MUSTT]; and the Sudden Cardiac Death in Heart Failure Trial [SCD-HeFT]. (See symbols at top of figure for identification of trials from which data are posted). The *x*-axis shows duration of ICD-related reduction in mortality after which there is no benefit and the *y*-axis shows cost effectiveness. **A,** lifetime costs that were included in survival curves were assumed to be parallel after the time period. In this analysis, the costs for both treatment strategies continue through the patient's projected lifetime. The base-case assumption is that the benefit lasts a lifetime (*arrow*). **B,** both costs and benefits are assumed to stop at the specified time. QALY, quality-adjusted life-year. (Redrawn from Sanders GD, Hlatky MA, Owens DK: Cost-effectiveness of implantable cardioverter defibrillators. N Engl J Med 2005;353:1471-80.)

than when one is actually in the situation. Further exploration of potential background modifiers such as percentage increase in life years or percentage increase in QALYs have been suggested and might be considered appropriate in some cases.[144]

Cost-Benefit Analysis

Although cost-benefit analysis is favored by many economists, it is the least used method by health economics analysts. Here the numerator is cost, as in CEA, but the denominator is expressed in the dollar value of medical benefits.[115,145] There are obvious difficulties in this form of expression, especially for physicians. A formula for cost-benefit analysis is as follows:

$$\frac{\Delta \text{ Cost}}{\Delta \text{ Benefit}} = \frac{\$10{,}000}{\$2{,}000}$$

$$\text{Net Cost} = \Delta \text{ Cost} - \Delta \text{ Benefit} = \$10{,}000 - \$2{,}000 = \$8{,}000$$

A $\Delta C/\Delta B$ of 1 with a consequent net cost of 0 might be considered desirable.

Decision Analysis

CEA requires a method of organizing the cost and effectiveness components of a medical strategy in a precise manner to enable the quantification of outcomes and assignment of costs. The method used is *decision analysis*.[146-148]

In decision analysis,[149] a complex situation is distilled into all of its smaller components and organized in a *decision tree*. The decision tree maps out how populations move through various disease states and displays the diagnostic and therapeutic strategies, the probabilities and consequences of each strategy, and in the case of CEA, the costs. In this construct, the *Markov model* has been used to consider changes in state or *transitions* of a population as it moves through a disease process (e.g., from health to acute MI to recovery).[146,148,150]

Figure 1–19 is a decision tree of the CEA of coronary artery disease (CAD) preventive treatment in high-risk (A) and low-risk (B) patients. It is a highly simplified tree based on a previously published hypothetical example.[151] In the tree, there are two types of branch points:

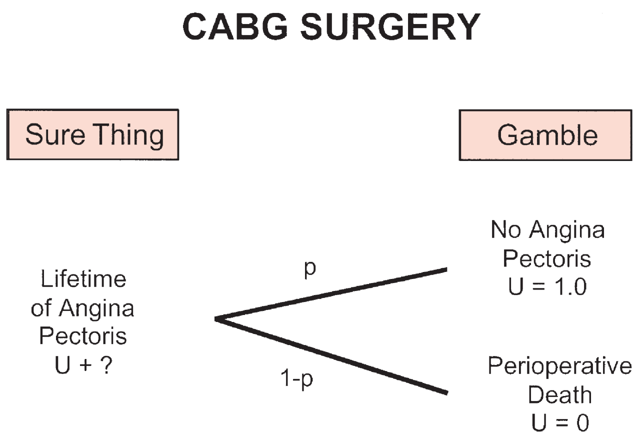

Figure 1–18 Standard gamble of J Von Neumann and O Morganstern (Theory of Games and Economic Behavior. Princeton, NJ: Princeton University, 1944) showing two choices. *Left*, The choice (sure thing) represents a lifetime with the disease, such as coronary artery disease. *Right*, Choice is a gamble to perform coronary artery bypass graft (CABG) surgery with two probabilities: that the patient will return to normal health (p) (*top*) or there will be a perioperative death (1-p) (*bottom*). One varies (p) until the indifference probability, which represents the utility, is reached. For example, if the subject cannot choose between living with angina and an 80% chance of perfect health versus a 20% chance of immediate death, the utility (U) is 0.8. (Redrawn from Kupersmith J, Holmes-Rovner M, Hogan A, et al: Cost-effectiveness analysis in heart disease, Part 1: General principles. Progr Cardiovasc Dis 1994;37:161-84.)

1. *Decision nodes* (squares)—branch point where a decision has to be made—in this case, the decision is *to* use or *not to* use a CAD-preventive regimen;
2. *Chance nodes* (circles)—branch point where one of several states or events may occur that are beyond the decision maker's control. Occurrences here include death, acute MI, other disease states, and alive and well.

Every occurrence (i.e., every limb at a chance node) is assigned a probability. In Figure 1–20A, the probability that a high-risk patient receiving preventive therapy dies in 1 year is 0.05 versus 0.10 in patients not receiving the therapy; for low-risk patients (see Fig. 1–20B), the corresponding values are 0.005 and 0.010. (Other assumptions are noted in the figure legend.) Each limb is also assigned a cost ($2,000 for preventive therapy, $20,000 for CABG, and so on.). The sum total of all probabilities and costs then forms the CEA formula. Results in this hypothetical example are that the cost effectiveness of preventive therapy is $12,800/YLS in high-risk patients and at a much less favorable $216,900/YLS in low-risk patients. This 17-fold more favorable cost effectiveness in the high-risk group results from the higher mortality rates (with an attendant greater gain in effectiveness). In addition, because of high morbidity rates at high risk, expensive interventions and surgical procedures are more common, leading to more substantial monetary gain from the aversion of such interventions and procedures, as in the case of enoxaparin, which is dominant in acute coronary syndrome patients.[125]

Limbs of the tree become much more complex than shown in Figure 1–19 as one elaborates on all the nuances of diagnosis and care, although it is difficult to include every last nuance. There are generally simplifying assumptions[152,153] and there may also be components of intuitive thinking that are not captured by decision analysis. For example, one nuance might be that not only will there be fewer acute MIs with preventive treatment but also the MIs will be less severe. The tree must also be compact and understandable[154] and a given nuance may have little impact on the overall results (or be addressed by sensitivity analysis)(see later).

Decision analysis models have been compared with the recommendations of expert clinicians. In one study, QALY gain and cost/QALY were compared with appropriateness scores developed by an expert panel on whether or not to undertake post-discharge coronary angiography within 12 weeks after MI. There was a significant correlation between expert-opined appropriateness of angiography and both QALY gain (Spearman rank correlation coefficient, 0.58, $P < 0.001$) and cost effectiveness (-0.66, $P < 0.001$). No indications that clinicians deemed appropriate were valued at more than $50,000/QALY, whereas clinicians were more conservative than the decision analysis model in certain asymptomatic patients (i.e., intervention considered inappropriate but valued at less than $50,000/YLS).[155]

Sensitivity Analysis

Because of the spectrum of data used in CEA , there is often uncertainty, and to address this uncertainty, one uses *sensitivity analysis*. Here, one varies the assumptions made in the base case on specific aspects of the analysis and then repeats the calculation. One asks the question "What if" and then determines whether results were critically dependent on the assumption.[107,156] Figures 1–20 through 1–23 show a series of *one-way* sensitivity analyses (i.e., testing of only one assumption) based on the data in the decision tree shown in Figure 1–19. Figure 1–24 is a two-way sensitivity analysis.

Figure 1–20 shows the effects of varying the cost of preventive therapy in high-risk (A) and low-risk (B) situations. The cost-effectiveness results are linearly related to the cost of prevention and *sensitive* to it; that is, cost effectiveness varies greatly as the cost of prevention changes. Of interest is that the "break-even" threshold of prevention is the cost at which cost savings of prevention (e.g., reduction of CABG, PTCA, acute MI, and so on) in totality equals the costs of prevention. This is lower in the high-risk situation, $108 versus $913. The other value of interest is what the cost of prevention would have to be in the low-risk situation for it to be "cost effective," $50,000/YLS (in this example)—in this case, $544.

Figure 1–21 shows the effect of changing the percent mortality benefit in high-risk (A) and low-risk (B) situations. At base case, the mortality benefit was assumed to be 50%. The "cost effective" threshold ($50,000/YLS) for high risk is a mortality benefit of only 11.3%, whereas for low-risk situations, cost effectiveness is still $121,000/YLS at a mortality benefit of 90%. Figure 1–22 shows the sensitivity of changing the assumptions related to the cost of CABG (A), PTCA (B), and acute MI (C). Cost effectiveness is improved (i.e., at a lower value) as the costs of these eventualities rise and there are more savings from averting them, but the model is relatively insensitive to the changes in these costs. Figure 1–23 shows the

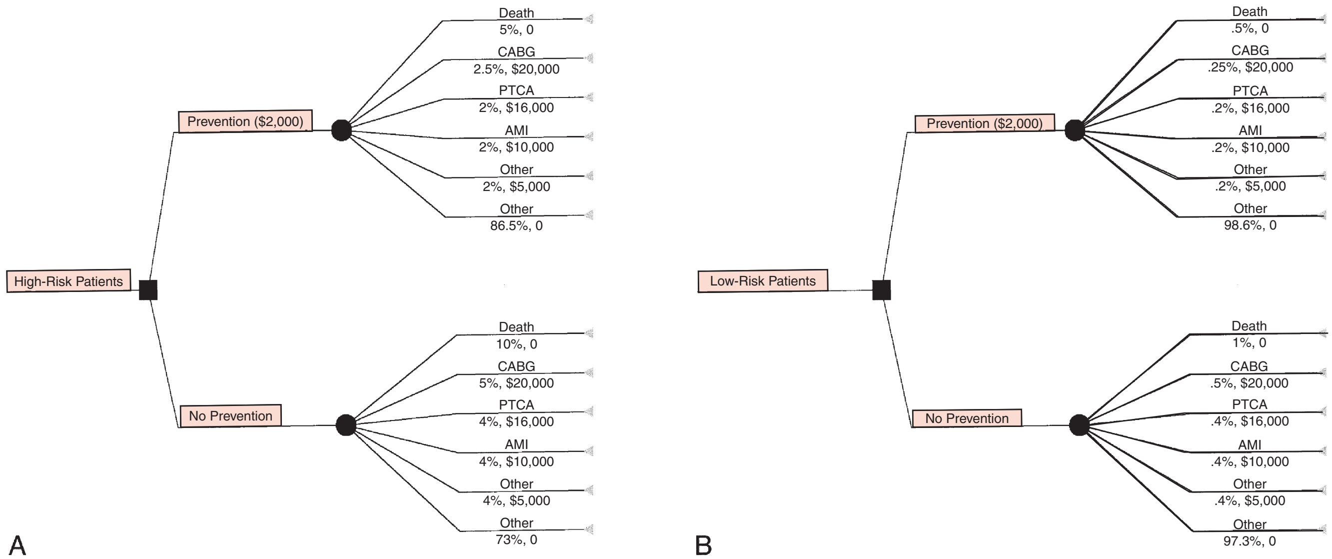

Figure 1–19 Decision trees of cost effectiveness (cost/years of life saved [YLS]) of preventive therapy for coronary artery disease in high-risk (**A**) and low-risk(**B**) patients. Decision trees are hypothetical for explanation purposes only and not based on derived data. Prevention is assumed to cost $2,000. Decision nodes (*filled square*) are whether or not to use preventive therapy. Chance nodes (*filled circles*) show occurrences of death, coronary artery bypass graft surgery (CABG), percutaneous transluminal coronary angioplasty (PTCA), acute myocardial infarction (AMI), other disease states, and alive and well with percentages and long-term costs of each. In this example, diagnostic tests are considered within the overall cost of preventive therapy, as are any other events and treatments that an individual might have received, such as complications of CABG, AMI, and so on. Time horizon is 6 years, there is no discounting, all patients are assumed to die at mid-year, numbers are annual figures and preventive therapy is assumed to reduce death and events by 50%. Cost effectiveness is $12,800/YLS in high-risk and $216,000/YLS in low-risk groups. (Basic concept from Goldman L, Garber AM, Grover SA, Hlatky MA: Task force six, cost-effectiveness of assessment and management of risk factors. J Am Coll Cardiol 1996;27:964-1097, with modifications.)

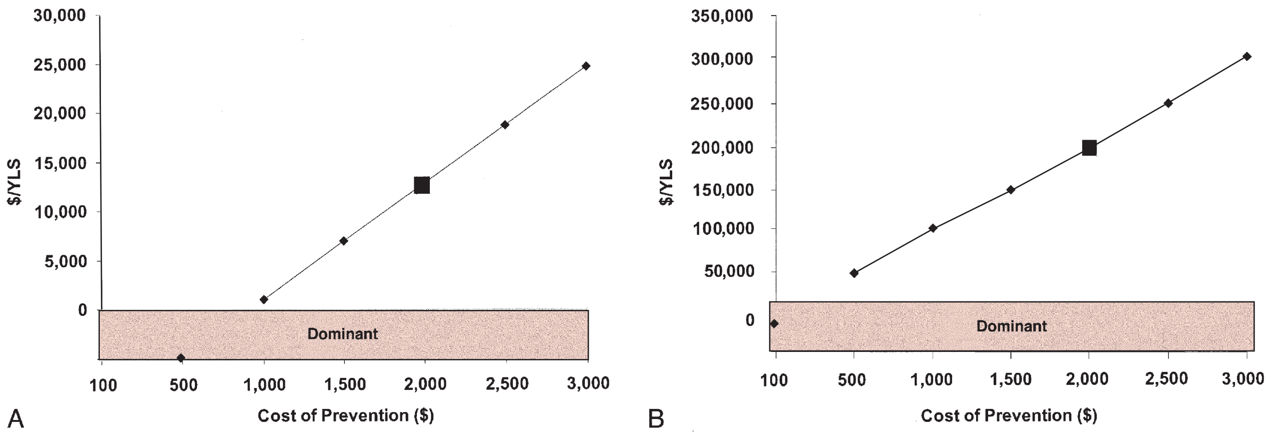

Figure 1–20 Sensitivity analysis showing effects of varying cost assumptions of preventive therapy on cost effectiveness in high-risk (**A**) and low-risk (**B**) populations shown in Figure 1–19. At base case (*filled square*), the cost is $2,000. Cost effectiveness varies greatly and linearly with the cost of preventive therapy (i.e., cost effectiveness is sensitive to changes in cost of prevention). The cost threshold where prevention becomes dominant (i.e., the "break-even" point is $108 in high-risk and $913 in low-risk patients). The threshold cost for preventive therapy being "cost effective" (i.e., $50,000/YLS) at low risk is $544. Note differences in vertical scales in **A** and **B.**

results of changing assumptions regarding the mortality in the "no-prevention" population without changing the proportional mortality benefit of prevention. At base case, mortality rate in the no-prevention population was assumed to be 5% in the high- and 0.5% in the low-risk situations. The threshold for a cost-effective intervention ($50,000/YLS) is 1.9% population mortality rate. This number could be interesting for policy makers to decide which populations should have such interventions (e.g., in a primary prevention study).

Figure 1–24 is a *two-way sensitivity analysis* in which the assumptions both on costs of prevention and on mortality in the no-prevention group are varied. Here, one can elaborate zones of dominance, favorable cost effectiveness, and so on. In Figure 1–24, there is a zone of dominance (to the right of

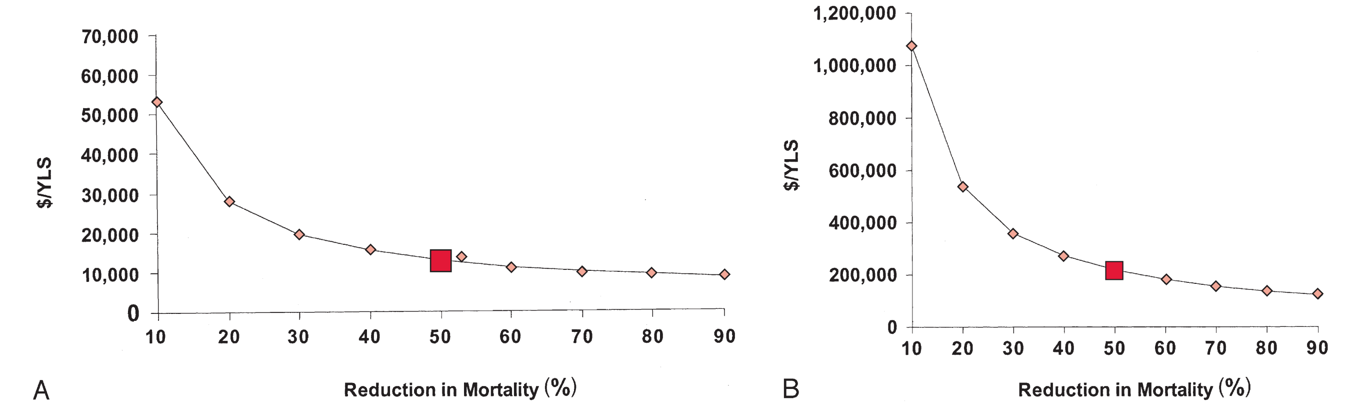

Figure 1–21 Sensitivity analysis of altering benefit assumptions (% reduction in mortality) of preventive therapy in high-risk (**A**) and low-risk (**B**) populations shown in Figure 1–19. Base case benefit is a mortality reduction of 50% (*larger square*). Cost effectiveness changes in both instances become more profound as one moves to a mortality benefit <30%. Of particular interest is that the threshold level for the intervention being "cost effective" (<$50,000) in high-risk populations is still a very modest mortality gain, 11.3%. However, in low-risk situations, even at a mortality benefit of 90%, cost effectiveness is still $121,000/YLS (years of life saved).

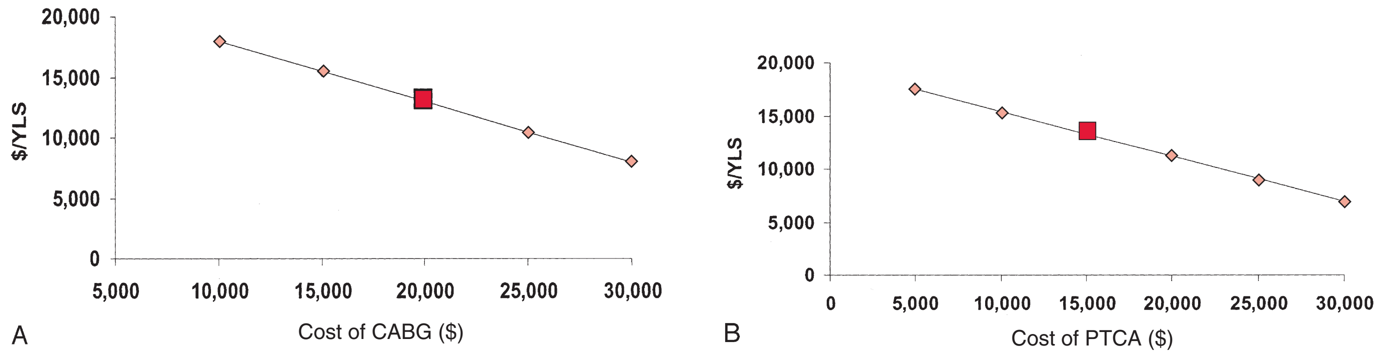

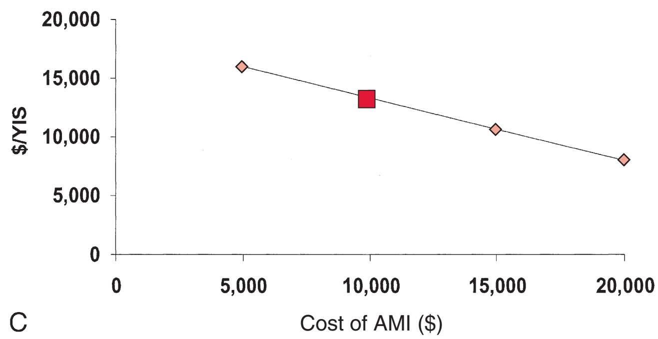

Figure 1–22 Sensitivity analysis of varying cost assumptions of coronary artery bypass graft surgery (CABG; **A**), percutaneous transluminal coronary angioplasty (PTCA; **B**), and acute myocardial infarction (AMI; **C**) in high-risk populations shown in Figure 1–19 (*filled squares* show base case). Cost effectiveness is relatively insensitive to these changes (i.e., still favorable even with a wide range of assumptions).

break even), a cost-effective zone (between break even and $50,000/YLS), and a zone where there is less favorable cost effectiveness (to the left of $50,000/YLS). *Three-way sensitivity analysis* can also be performed.[157]

Statistical Analysis

Traditional statistical analysis, and therefore meaning of a particular result, is probably less well developed for CEA than for other types of study, such as RCTs. Confidence interval determination is now a more frequent component of CEA.[69,158,159] Nonparametric bootstrap analysis is commonly used.[160,161]

Longevity Cost Inclusions

If a medical intervention prolongs life, there is added cost. In analyses of CABG, for example, one uniformly includes costs related to CAD during the extended life period. However, other diseases, such as cancer, may also occur and there is dispute as to inclusion of these particular costs, although they do not change the results much.

Perspective

Perspective reflects who pays the bill or who may receive benefits from efficiencies. *Payers* may include hospitals, health

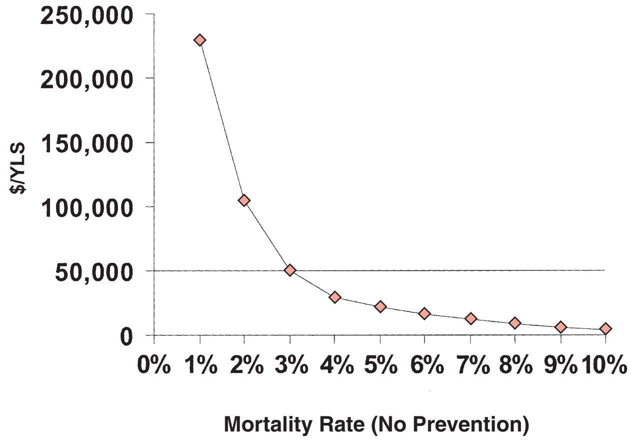

Figure 1–23 Sensitivity analysis of assumptions regarding the mortality rate in the no-prevention population in Figure 1–19 with mortality benefit assumed to remain at 50%. At base case, mortality was assumed to be 5% in the high-risk and 0.5% in the low-risk groups. Threshold for "cost-effective intervention" ($50,000/years of life saved [YLS]) is a mortality in the no-prevention population of 1.9%.

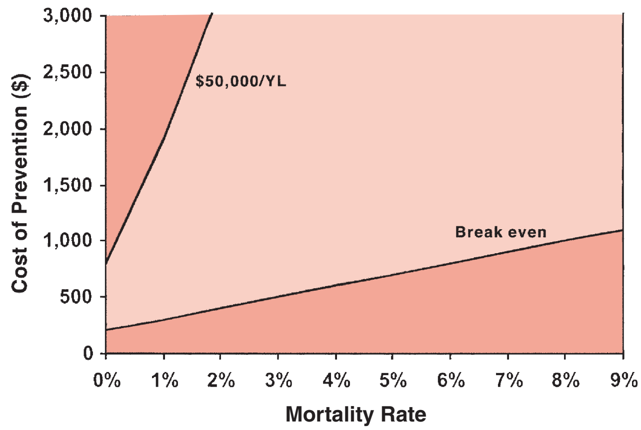

Figure 1–24 Two-way sensitivity analysis showing effects of both cost of preventive therapy and death in the low-risk population group of population shown in Figure 1–19. Shown are identity lines for "break even" and a cost effectiveness of $50,000/years of life saved (YLS).

maintenance organizations, providers, patients, or society as a whole. At times, perspectives may clash. For example, a shortened hospital length of stay of a patient benefits the hospital because payments from insurance companies are prospective (via diagnosis-related groups) (DRGs) and similar regardless of the length of stay. For the patient, it may be economical to stay in the hospital because there are many out-of-pocket costs to avoid, including possible home care. From a societal perspective, the sum of hospital and long-term outpatient costs should be considered.[162,163] As can be seen, each entity may view costs from the perspective of its own particular "silo" and the general welfare may be a lesser consideration. It is recommended that societal perspective be the standard for analyses, in part to ensure comparability.[164] However, an individual entity (hospital, health care plan, and so on) may find CEA very useful in making rational allocations of resources from its own perspective.

Discounting

Discounting is a method to equalize present and future costs.[107,115,146,155] In both economics and life, future benefits and adversities are not valued the same as those of the present. For example, we would rather die in the future. In another example, technologic enhancement for the treatment of coronary artery disease may be both more possible and cheaper in the future, devaluing the role of cholesterol lowering. Therefore, money spent "now" for benefits is worth more than money spent in the future. The method used for equalizing time is *discounting* of both future costs and effectiveness. A 3% per year discount of future items is recommended (a reflection of average yield in public investments), although many past analyses have used 5% per year.

Because the timing of cost and benefits of a particular intervention varies, the impact of discounting also varies. In the case of long-term drug treatment (e.g., for hypertension) costs are relatively uniform over time (e.g., drug costs, intermittent diagnostic testing, complications) and benefits are delayed. For surgical or procedural interventions, there is a large initial and much more modest long-term cost, and benefit starts immediately. Here, one gets a return over time for the initial investment. The overall cost effectiveness of these two types of medical interventions may be comparable, but a higher discount rate has more of an impact in devaluing the benefits of prevention because these benefits are more in the future.

Subgroup Analysis

Analyses may be targeted on the basis of risk (see Fig. 1–19) but also to specific subgroups, such as women,[152] minorities, and different age groups. For age, the interaction is complex. In elderly persons, there is higher risk (associated with more favorable cost effectiveness of an intervention) and shortened LE and tendency toward lower efficacy coefficients (both associated with less favorable cost effectiveness).

Generalizability of Data

Although issues related to reliability of the data applied to CEAs are in part addressed by sensitivity analysis, some remain. One of the most important issues is generalizability of data to the particular clinical situation under analysis. For example, population cohorts that form the basis of a particular CEA may have individual peculiarities in disease severity, approaches to quality, medical care, income, perceptions, ethnicity, geography, domicile of origin, and the nature and size of the local health care delivery system—all influential issues on both the cost and effectiveness sides. Styles of practice may also vary, especially for interventional procedures, among individual physicians[165,166] and in different regions of the country.[167]

Costs may also be site or regional specific. Although the medical marketplace has created some site uniformity, there remain large site and regional differences depending on the degree of managed care penetration, negotiating leverage, purchasing power, competition among physicians, and special nature of academic institutions. One approach to address

these differences is *microanalytic modification of costs* that are setting specific.

Efficacy Versus Effectiveness

An important distinction related to generalizability is that between *efficacy* and *effectiveness* data. The population cohort of the typical RCT may have nonrepresentative characteristics, such as high compliance to medication, possibly greater disease severity, limited comorbidity, narrow demography, possible incentives in entering the trial, and others, that may set it apart from the general population (selection bias). This type of RCT determines an ideal *efficacy*, that is, what the intervention "can do." The CEA is a broader study than the RCT and requires *effectiveness*, i.e., what the intervention "will do" in broad populations where compliance is variable, demography is varied, and comorbidity is common. Megatrials such as Global Utilization of Strategies to Open Occluded Coronary Arteries (GUSTO)[146] overcome some of these problems, but case selection at the individual sites can still skew the study population to some degree. Increasing interest is developing in the concept of pragmatic clinical trials[168] in which every effort is made to answer the effectiveness question in the context of randomization. The goal is to enroll a diverse study population in a comparison of clinically relevant alternatives that measure a broad range of health outcomes.

An example of the possible differences in results between CEAs based on efficacy and effectiveness data is shown in Figure 1–16.[118] Here a sensitivity analysis is used to contrast results from data derived from an RCT (efficacy) with those estimated from community-based observational data (effectiveness) in a CEA of primary angioplasty in acute MI. Of interest is the less favorable cost effectiveness when results are based on community-derived observational data in situations where stresses have to be added to the system to perform primary angioplasty (e.g., adding night call or an additional redundant or needed laboratory [where the lesser efficiency emerges only as the volume of acute MIs declines]).[118] Although in Figure 1–16 the differences in results between RCT and community-based data depend on volume , in other instances, it may be apparent in all situations.

Bias

With all of the these considerations regarding data and because CEA often occurs away from the safe harbor of the RCT, the issue of bias[169] has arisen especially in relation to selection bias and fairness regarding items not captured in the analysis. In constructing the analysis, what costs are included? Which data base is used for effectiveness? Key assumptions, judgments, and constraints that drive recommendations must be explicit and transparent.[170] What are the implicit and explicit budget constraints, and is the analysis transparent on this and other issues?[171] It is important to be vigilant in these areas, especially because the analysis may ultimately guide or even determine policy and may benefit the entity undertaking the analysis.

Standardization of Cost-Effectiveness Analyses

As indicated earlier, the basic purpose of CEA is to compare medical interventions and to do this, one must first address the issues raised above regarding generalizability, bias, cost analysis, and so on. One then needs standardization of technique. Because the methodology used in CEAs has varied, the U.S. Public Health Service in 1996 convened a panel on cost effectiveness and health in medicine to recommend a standardized approach.[108,164,172,173] They recommended that in all CEAs, there should be a *reference case* analysis that incorporates in its methodology the specific individual recommendations of the panel and is available for comparisons with other analyses. In the reference case, one should use societal perspective, CPI inflation-adjusted costs, indirect as well as direct costs, a 3% discount (but also provide sensitivity analysis for 5%), confidence intervals, and community preference QALYs. Inclusion of costs for unrelated diseases in years of extended life is optional.

Evidence suggests that the 1996 report of the U.S. Panel on Cost-Effectiveness in Health and Medicine had some impact on practice.[174] The use of cost effectiveness and related economic analysis techniques has improved and expanded over the past few years, as have efforts to synthesize and interpret results systematically. The United States Preventive Services Task Force (USPSTF), convened in 1998, built on the recommendations of the panel and two prior USPSTF Task Forces, to enhance recommendations intended for the general primary care situation by

1. Proposing a systematic approach for rating the quality of evidence; rating internal validity of each study as good, fair, or poor, based on explicit criteria; using expert stakeholders (topic team) to rate as good, fair, or poor, aggregate internal validity, external validity, and coherence/consistency of the *body* of evidence, weighting studies based on quality and explaining rationale with brief narratives; considering magnitude (effect size) separately from evidence quality but using both issues in making overall recommendations
2. *When quality of evidence is judged to be good or fair*, calculating net benefit (benefits minus harms of a service)
3. Considering benefit from both the individual and population perspectives and preparing outcomes tables that display both outcome frequency and degree of certainty about the information
4. Where possible, considering total economic costs that result from providing a service, both to individuals and to society.[175]

Evidence-based practice centers are using this approach to incorporate information about cost effectiveness into their evidence syntheses.[176] Each analysis considered should be prepared according to current guidelines, and the perspective, time line, and uncertainty around estimates should be openly and clearly stated.[177]

Vehicles for Making Comparisons—League Tables and Thresholds

Ordinarily one compares medical interventions in a *league table* which, as indicated earlier, is a rank order list of the cost effectiveness of a number of medical interventions.[109] Another approach is to use thresholds to set allocation rules (i.e., to aim at certain targets similar to the targets illustrated in the prevention example earlier, rather than merely making a list). The use of thresholds can enhance transparent and consistent

decision-making.[178] The threshold approach also may be more practical than league tables and mathematical programming techniques because it requires less data and the cost of collecting the additional data may not be worth the expense.[179]

Uses of Cost-Effectiveness Analysis

In its ideal, CEA can help form global health care policy decisions to determine and prioritize the most cost-effective interventions, to deliver these interventions, and to obtain the best possible health in the population for the health care dollar (i.e., the most QALYs for the money). It has received this sort of use in Australia,[180] Canada,[181] and Europe.[182] However, methodological issues[183,184] including those related to standardization[185] and the quality of systematic reviews,[186] the fact that data are not available for all health care interventions, the dearth of appropriate information systems, the difficulty of conveying the degrees and implications of uncertainty in findings,[187] and the lack of clear agreement on policy goals[170,188] have limited the impact of CEA in health care policy decisions. In addition, even a highly cost-effective intervention may be expensive and not affordable. There is an important question of when we make decisions on the basis of cost and when to use cost effectiveness. What is the role of cost in public decision-making?[189] Can we afford expensive but cost-effective treatments or diagnostic tests?

Value judgments also create problems in the use of CEA in policy decisions. For example, is a small benefit for a large number better than a large benefit for a small number? How much should one do for those with short LE? How do we value life versus quality of life? What populations will benefit from a given therapeutic intervention? In addition, technologies and drugs become obsolete, are upgraded and updated, and change in price due to efficiencies, loss of patent protection, and competition. Technologies also have large start-up and development costs, which decline over time. If we perform CEA early and include all these costs, there may be an unrealistic assessment and premature abandonment of a useful intervention.

Overall, a wide range of views exist on the use of CEA, and on the critical obstacles to its wider use. Political factors, technical factors, lack of trust between potential sponsors and users of analyses, lack of training among study consumers, and legal factors are among the reasons more moderate use of CEA in the United States has prevailed.[190] In general, CEA has been used to organize thinking and to aid decision-making (e.g., by the Department of Veterans Affairs in formulary management, by the U.S. Food and Drug Administration and in practice guidelines)[191] rather than as the prime mover in policy. CEA can be used to improve efficiencies, to elucidate and inform specific aspects of an intervention or specific targeted patients, to set prices of drugs or technologies, to create and evaluate incentives, and to constantly test our intuitive assumptions, which may be incorrect (e.g., prevention is not always cost effective and high-technology procedures often are cost effective).

Chapter 2

The Use of Cardiovascular Drugs: Pharmacological Principles

Stanley Nattel

CHAPTER CONTENTS

This chapter discusses the basic principles that govern the response to cardioactive drugs (see Appendix 1 for a comprehensive list of drugs used in cardiovascular medicine). The general factors that determine the response to a drug are indicated in Figure 2–1A. The factors that determine the relation between drug dose and drug concentration in the plasma are termed *pharmacokinetic factors*. The factors that determine the relation between plasma concentration and drug action are termed *pharmacodynamic factors*.

PHARMACOKINETIC FACTORS

Figure 2–2 summarizes the processes that occur following the administration of any drug. The administration of a drug produces concentrations in a central compartment of blood and highly perfused organs. The drug can be administered by a variety of routes. Most commonly, drugs are administered orally or by subcutaneous, intramuscular, or intravenous injection. The latter are generally referred to as parenteral routes, because they avoid the gastrointestinal (GI) barrier and result in complete or near-complete delivery to the circulation. Occasionally, other routes may be used, such as the buccal, anal (suppositories), or sublingual route. Administration by these alternative routes also bypasses gastrointestinal barriers.

ORAL BIOAVAILABILITY (F)

The GI system absorption of drugs may limit the availability of active compound after oral administration, either because of poor penetration across the mucosal GI barrier (particularly for hydrophilic compounds not subject to active GI transport) or because of rapid first-pass metabolism across the liver. Ouabain, for example, is a digitalis glycoside that is so fat insoluble that it fails to cross mucosal membranes and is useless by oral administration. All compounds crossing the GI mucosa pass through the liver via the portal veins before reaching the systemic circulation. Therefore, rapidly metabolized drugs may be converted so quickly into inactive metabolites (first-pass effect) that they fail to achieve clinically significant quantities in the blood. Lidocaine, for example, crosses the GI mucosa well but is so rapidly metabolized that it is useless as an oral antiarrhythmic.

Bioavailability refers to the fraction or percentage of active compound that reaches the systemic circulation and can achieve the desired clinical effects (often expressed as the fraction, F, of an administered dose that reaches the systemic circulation). Drugs with bioavailabilities lower than 10% generally reach the systemic circulation in insufficient quantities to be effective on oral administration. Drugs with high bioavailability (>80%) are very well absorbed and are not subject to variable responses related to oral absorption. Drugs with limited but acceptable bioavailability may be associated with drug interactions related to their incomplete availability. For example, digoxin has limited bioavailability and can be adsorbed by compounds such as cholestyramine, causing decreased GI availability and a reduced therapeutic response. It is important to distinguish between gastric absorption and functional bioavailability. For example, lidocaine is very well adsorbed after oral administration. However, before it can reach the systemic circulation it has to pass through the liver, where it is rapidly metabolized to byproducts that lack antiarrhythmic efficacy but possess toxic potential. Therefore, lidocaine is not useful as an oral agent. The term *bioavailability* should really be restricted to bioavailability of the compound administered or of that compound and its active metabolites.

In some cases, limited oral bioavailability is used to therapeutic advantage to limit the distribution of a drug to the GI tract. One example is cholestyramine, which acts by binding cholesterol in the gut, promoting its elimination and decreasing serum cholesterol. Its lack of oral absorption makes cholestyramine free of adverse systemic effects. Another example is sodium polystyrene sulfonate (Kayexalate), which binds potassium in the gut and promotes its elimination without any systemic absorption.

VOLUME OF DISTRIBUTION

Following delivery to the blood, drugs are distributed to other tissues. After intravenous administration, many drugs are

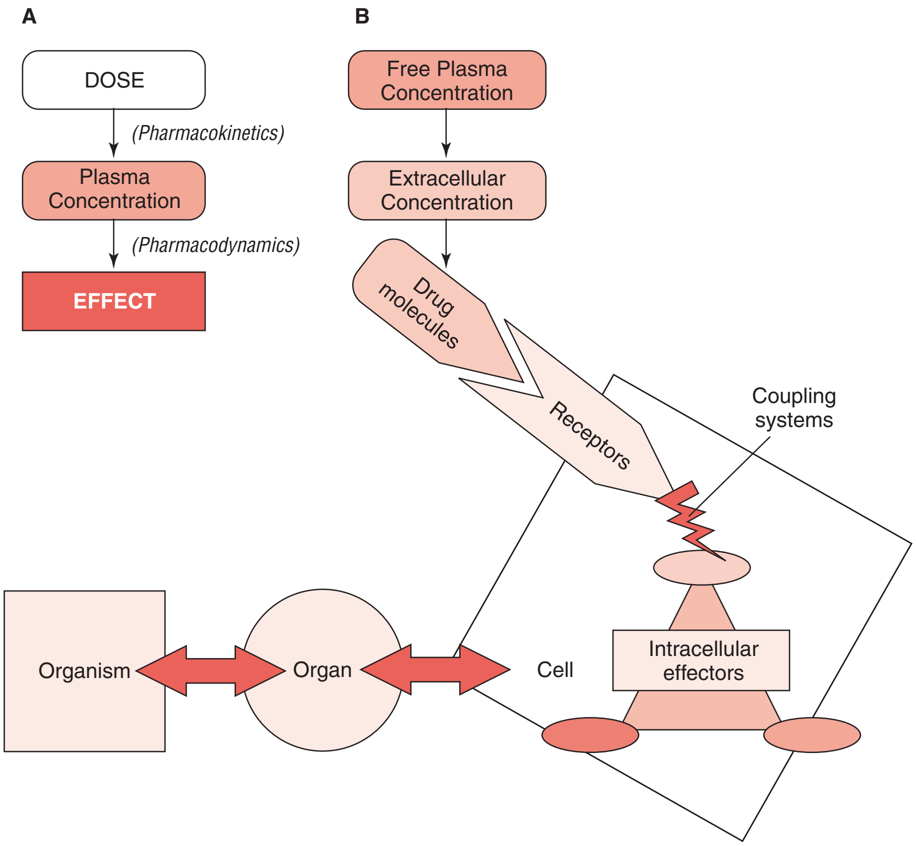

Figure 2–1 **A,** Relation between drug dose and effect. The plasma concentration-dose relation is determined by pharmacokinetic factors, whereas the plasma concentration-effect relation is determined by pharmacodynamic factors. **B,** A schematic showing the processes that mediate the effects of a drug and that determine the relation between plasma concentration and drug effect.

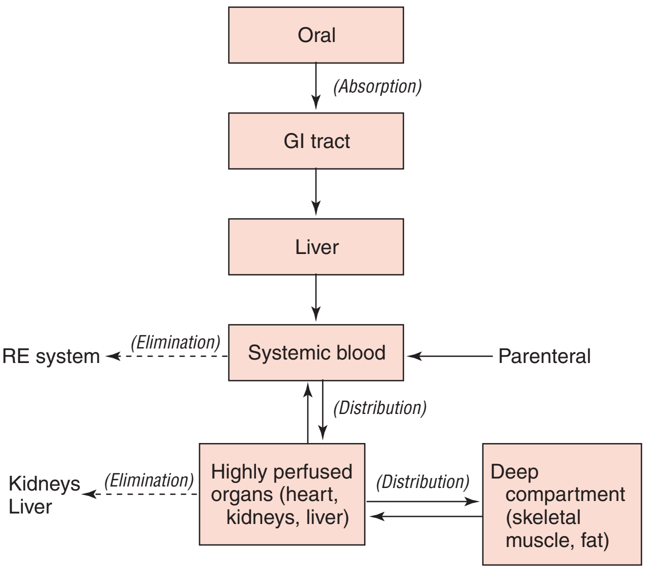

Figure 2–2 Processes that determine the disposition of a drug following administration. GI, gastrointestinal; RE, reticuloendothelial.

distributed rapidly to highly perfused organs (such as the heart and liver), but distribution to less well perfused organs (e.g., skeletal muscle) may take longer. The blood and highly perfused organs are referred to as the central compartment. Immediately after distribution to the central compartment, concentrations may be relatively high, and they decrease rapidly by tissue redistribution, generally with a half-life ($t_{1/2}$) in the range of 5 to 10 minutes. This very rapid decrease in drug concentrations should not be confused with the subsequently slower decrease caused by biotransformation in the liver to inactive metabolites or elimination by renal excretion. Some drugs (e.g., amiodarone) are associated with an even slower second phase of distribution to adipose tissues.

The volume of distribution (V_d) indicates the volume into which the body load of drug would need to be distributed to give the plasma concentration measured after complete distribution. Drugs with a V_d of less than 0.2 L/kg body weight (i.e., less than 14 L for the average adult male) are largely confined to the intravascular space. Drugs with a V_d of greater than 10 L/kg body weight have an extensive peripheral distribution, most commonly in adipose tissue. One striking example is amiodarone, with a V_d of 66 L/kg. The affinity of amiodarone for lipids is so great that prolonged loading is necessary to saturate the body's lipid tissue storage capacity at therapeutic plasma concentrations. This explains, at least in part, the drug's very slow onset of action after the onset of daily dosing, requiring the use of complex loading dose regimens to more rapidly achieve therapeutic effects. The extensive tissue distribution of amiodarone also contributes to its very slow elimination from the body (see later).

PROTEIN BINDING

Many drugs are bound in the blood to plasma proteins, including albumin and α1-acid glycoprotein. In general, protein-bound drug is not available to diffuse into the extra-

cellular space to bathe target tissues and is, therefore, inactive. When relating pharmacological studies of drug actions in in vitro systems to therapeutic drug concentrations, it is important to remember that only drug that is not bound to plasma proteins is physiologically active. Therefore, in vitro concentrations should be related to free plasma drug concentrations ([100% minus protein-bound percentage] times total therapeutic concentration) rather than the total plasma drug concentration during therapeutic administration. Drugs with high protein binding can be displaced by drugs that bind to the same protein and have high therapeutic plasma concentrations, such as sulfa compounds. The latter achieve high enough concentrations to produce near saturation of the considerable plasma protein binding capacity, thereby potentially displacing other drugs highly bound to the same proteins, increasing their free concentration and increasing their activity. An important example is warfarin, which is highly protein bound and can be displaced by drugs such as sulfonamide antibiotics, potentially increasing anticoagulation and the risk of major bleeding.

ELIMINATION AND $T_{1/2}$

Most drugs are eliminated via the liver, the kidneys, or a combination thereof. Disease of the drug-eliminating organ decreases the rate of drug elimination for a given body load and plasma concentration. The maintenance dose must be decreased accordingly or the drug load (and plasma concentration) may increase to the point that potentially toxic effects may be produced. For some drugs, such as warfarin, the hepatic enzyme metabolizing system is indicated because specific enzymes may be inhibited or have their activity induced by specific interacting drugs. This type of interaction is of particular importance for drugs such as warfarin, which have a low therapeutic index and great risk of adverse interactions involving enzyme inhibition (which can precipitate a potentially dangerous bleeding diathesis in patients taking warfarin) or induction (which can reduce warfarin effects to dangerously low levels in patients with a strong indication such as prosthetic cardiac valves).

The $t_{1/2}$ is the drug half-life or time for plasma drug concentrations to decrease by 50%. The $t_{1/2}$ can refer to the rate of tissue redistribution after intravenous administration (the so-called α- $t_{1/2}$) or the rate of elimination following full distribution through the body (the elimination or β- $t_{1/2}$). Elimination half-lives indicate the time for one half of the body load of a drug (or the corresponding plasma concentration) to decrease by 50%. Drugs with a narrow therapeutic index are often given at intervals less than the $t_{1/2}$ to avoid swings in plasma drug concentration greater than 50% (twofold changes).

The $t_{1/2}$ is useful to estimate the time course of changes in plasma concentration. It indicates the time required for plasma concentrations to decrease by 50% after drug discontinuation. Thus, if toxic effects appear, it will take one half-life for 50% of the drug to be eliminated and three half-lives for 87.5% of the drug to disappear from the body. This information is useful for estimating the time at which adverse effects may be expected to disappear after drug discontinuation. Steady-state drug concentrations require four to five half-lives after the onset of dosing or after any dose change. This knowledge may help to avoid misinterpreting responses before steady state has been achieved and may, therefore, help to avoid erroneous dose adjustments. If the organ of drug elimination is diseased, the half-life increases. Correspondingly longer intervals elapse before drug elimination and before steady-state conditions are achieved after beginning the drug or making a dose adjustment. These changes need to be considered in evaluating the time needed for adverse drug effects to cease after drug discontinuation and in estimating drug actions at presumed steady-state effects.

A final point is that, in exceptional cases, the elimination half-life is determined not by the organ of elimination but by extensive tissue stores. Amiodarone is a striking example. Amiodarone achieves extremely high tissue concentrations and is highly protein bound in the blood. Thus, even though the liver is quite efficient at handling the compound, little of the body load exists as unbound drug in the blood available for metabolic biotransformation. This explains the extremely long half-life of the drug, approximately 30 days, after the discontinuation of long-term oral administration.

PHARMACODYNAMIC FACTORS

Pharmacodynamic factors refer to factors that determine the relation between plasma drug concentration and drug effect. Figure 2–1B illustrates the general determinants of drug action at the cellular level. The drug in plasma equilibrates with drug in the extracellular space, producing an effective concentration equal to the free plasma drug concentration. Drug molecules then interact with receptors, which may be intra- or extracellular, and produce changes in intracellular effectors via a coupling system. Altered cellular function will affect the function of the organ, which in turn will alter the state of health of the organism. In some cases (e.g., certain ion channel blockers), coupling to intracellular receptors may not be necessary. Changes in any of the parts of this system (e.g. the number and affinity of the receptors, the activity of the coupling systems, the nature of intracellular effectors) can alter drug sensitivity on a pharmacodynamic basis.

Consider, for example, digitalis action. Digitalis acts by binding to and inhibiting the Na^+, K^+-ATPase in the membrane. The Na^+, K^+-ATPase pumps Na^+ out of the cell in exchange for K^+ which is moved into the cell, to maintain the physiological transmembrane ionic gradient. The positive hemodynamic actions of digitalis result from a tendency for intracellular Na^+ to rise when the Na^+, K^+-ATPase is inhibited. This Na^+ is handled by exchange for extracellular Ca^{2+} (via the Na^+, Ca^{2+}-exchanger, NCX), leading to increased total cellular Ca^{2+} that is handled by increased uptake into the sarcoplasmic reticulum (SR). Digitalis toxicity results when SR Ca^{2+} is so overloaded that spontaneous diastolic spillover from SR Ca^{2+} stores occurs, leading to Ca^{2+}-dependent arrhythmias. A variety of factors can alter the effect of digitalis to promote toxicity. For example, K^+ binds to Na^+, K^+-ATPase and reduces digitalis binding by an allosteric mechanism. If serum $[K^+]$ is reduced, there is less K^+ bound to the ATPase and digitalis action is enhanced, potentially leading to toxicity. If extracellular $[Ca^{2+}]$ is increased (increasing Ca^{2+} entry into cells), or if Ca^{2+} movement into the cell is enhanced (e.g., by catecholamines, theophyllines or acute myocardial ischemia), SR Ca^{2+} stores are increased, increasing the chances of digitalis-

induced excess cell Ca^{2+} loading and toxicity. If NCX activity is increased (e.g., in congestive heart failure) or Na^+, K^+-ATPase activity is reduced, the likelihood of digitalis toxicity is increased.

The pharmacokinetic $t_{1/2}$ should not be confused with the biologic $t_{1/2}$, which may be similar or quite different based on pharmacodynamic considerations. For antiarrhythmic drugs, with a tight concentration-response relation, the pharmacokinetic and biologic $t_{1/2}$ values are similar. On the other hand, for other compounds such as β-adrenoceptor antagonists, they may be quite different. A β-blocker achieves effects by blocking β-adrenergic receptors. The β-adrenoceptor binding is saturable, and low therapeutic concentrations of β-blockers achieve nearly complete saturation. A large increase in β-blocker dose does not produce greater effects because the receptors are already saturated; however, it greatly lengthens the time required after a dose for drug elimination to achieve subtherapeutic concentrations at which β-receptor binding (and blocking) decreases substantially. This principle explains, at least in part, why many drugs can be given at intervals much longer than their pharmacokinetic half-lives.

DOSE

In general, when a sustained effect is needed, maintenance doses need to replace the amount of drug eliminated from the body during the dosing interval. If one knows the desired body load at steady state (for a drug given by intravenous loading dose, this will simply equal that dose) and the percentage of drug eliminated over a dosing interval, one need only multiply the percentage eliminated by the body load to estimate the amount of drug that needs to be given (assuming 100% bioavailability) to maintain the body load constant. The simplest case is when the drug is given at an interval equal to the elimination half-life—then one need give one half the load every half-life to maintain a stable body load and plasma concentrations.

Maintenance doses need to be decreased when the drug-eliminating organ is diseased. In addition, the rate of drug removal from the body is related to the body load. For a given plasma concentration, the body load is generally related to body mass (usually lean body mass). Thus, maintenance doses need to be greater for larger individuals and decreased doses are required for very small patients. Elderly people often have smaller lean body masses and decreased renal function, so they usually require smaller maintenance doses, especially for drugs eliminated by the kidneys. Whenever possible, doses should be titrated to meaningful concentration-related biological effects such as therapeutic endpoints (e.g., International Normalized Ratio or INR for warfarin) or limiting dose-related adverse effects (e.g., hypotension for converting enzyme inhibitors in heart failure).

DRUG INTERACTIONS

Drug interactions can be pharmacokinetic (based on a change in free drug concentration) or pharmacodynamic (based on changes in target organ sensitivity to a given drug concentration). Pharmacokinetic interactions alter the way in which a drug is absorbed, distributed, or eliminated. Reduced GI absorption of a drug on coadministration with cholestyramine is an example of a pharmacokinetic drug interaction related to changed absorption. Reduced drug elimination because of inhibition of hepatic enzymes decreases dose requirements and prolongs drug half-life for a susceptible drug, whereas induction of a drug-eliminating enzyme has the opposite effects (increased dose needs and reduced half-lives). Displacement of a drug from sites of protein binding is an example of an interaction related to changed distribution.

Pharmacodynamic interactions most typically result from drugs with similar or opposite actions. For example, the enhanced bradycardia seen when β-blockers and Ca^{2+} antagonists are coadministered is a pharmacodynamic interaction that may produce adverse effects because of excessive effects of the combined actions of the two classes of drugs. Conversely, reduced efficacy of β_2-agonist bronchodilators in a patient treated with an oral β-blocker is an example of a pharmacodynamic interaction because of opposing drug actions.

PHARMACOGENOMICS

Pharmacogenomics is the study of the genetic factors that determine drug responses. Such factors can operate at either the pharmacokinetic or pharmacodynamic level, and account for a significant degree of the inter-individual variation that can lead to inefficacy or toxicity of an otherwise well-tolerated and effective dose of a drug. This is a rapidly developing field that promises to allow for great improvements in the safety and efficacy of drug therapy by taking into consideration genetic factors that affect dose requirements or the response in individual patients.

It is well recognized that there is substantial inter-individual variation in pharmacokinetic and pharmacodynamic determinants that can greatly affect drug sensitivity and response. The basis for this variation is often unknown, and environmental factors such as drug-metabolizing enzyme inducers and inhibitors are often quite important. However, there may be very clear genetic determinants that are identifiable and would allow for safer and more effective therapeutics. This is an active field of investigation and could be the subject of a voluminous chapter on its own. In the context of the present chapter, I will limit myself to simple illustrative examples.

Oral anticoagulation is strongly indicated for a variety of cardiovascular conditions, such as venous thromboembolism, atrial fibrillation (AF), and prosthetic cardiac valves. The margin of safety for oral anticoagulation is recognized to be narrow, with efficacy requiring international normalized ratios (INRs) of 2 to 3 for AF and 2.5 to 3.5 for mechanical heart valves, and risk of bleeding increasing progressively at INR > 4. Warfarin and other vitamin-K antagonist drugs act by inhibiting the generation of vitamin K from vitamin-K epoxide (Fig. 2–3). The synthesis of vitamin K decreases, leading to impaired vitamin K-dependent γ-carboxylation of glutamyl residues required for activation of a variety of proteins, including several key coagulation factors.

Inter-individual variability in the response to warfarin is great, leading to a risk of inefficacy in some cases and bleeding complications in others. There are important genetic determinants of warfarin sensitivity that act at the pharmacokinetic and pharmacodynamic levels (see Fig. 2–3). CYP2C9 is a

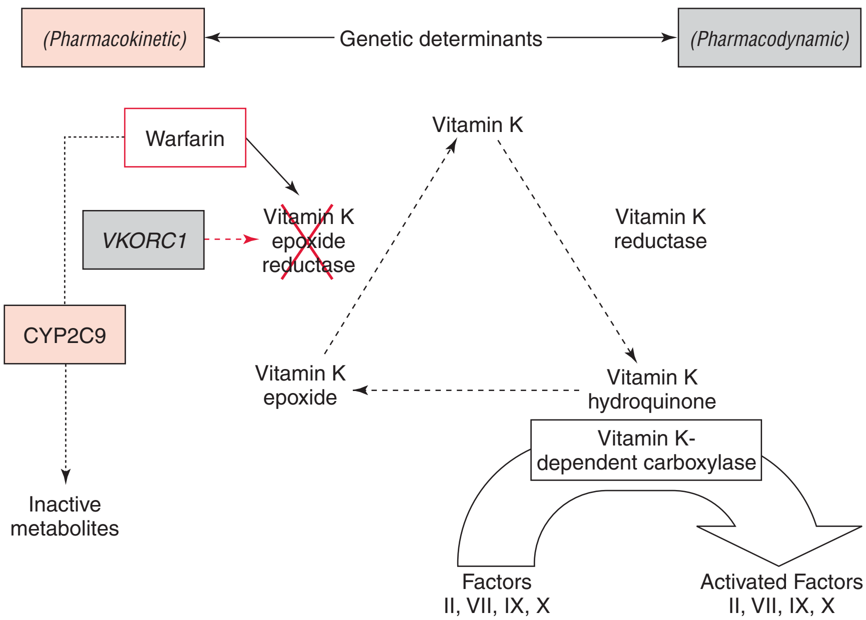

Figure 2–3 Schematic of vitamin K metabolism and its role in coagulation, along with mechanism of action of warfarin and two important pharmacogenomic determinants. Vitamin K is essential for γ-carboxylation of glutamyl residues on coagulation factors required for their activation. Warfarin inhibits vitamin K synthesis from vitamin K epoxide by acting on a crucial reductase enzyme. Key genetic determinants of sensitivity that act on warfarin pharmacokinetics (CYP2C9) and pharmacodynamics *(VKORC1)* are shown. For discussion, see text.

cytochrome P450 enzyme that biotransforms the active *s*-enantiomer of warfarin to inactive metabolites. Single nucleotide polymorphisms (population variants in single nucleotides) greatly affect CYP2C9 activity and can reduce enzyme activity 20-fold—substantially reducing warfarin dose requirements and increasing drug sensitivity/bleeding risk. Mutations in the gene (*VKORC1*) encoding vitamin K epoxide reductase (the enzyme on which warfarin acts) can cause severe warfarin resistance and increase dose requirements by an order of 10-fold. Single nucleotide polymorphisms in *VKORC1* are a significant and identifiable source of variation in vitamin K dose requirements in the population.

It is hoped that the genetic determinants of drug response can be identified for a wide variety of conditions and drugs—with the ultimate goal of obtaining patient-specific pharmacogenomic profiles that allow for safe and effective individualized prescribing.

CHAPTER CONTENTS

Gene Therapies for Cardiovascular Diseases: Where We Are and Where We Are Going

Luis G. Melo, Christopher A. Ward, and Victor J. Dzau

OVERVIEW

Despite the remarkable therapeutic advances of the last 30 years, cardiovascular disease (CVD) remains the major cause of disability and premature death in the Western World.[1,2] According to epidemiological data published by the National Heart, Lung, and Blood Institute, 20% of the population at age 40 is at risk of developing congestive heart failure (CHF) in their lifetime, and approximately 80% of the population with CHF younger than age 65 will die within 8 years of diagnosis.[2] These staggering statistics have serious socioeconomic repercussions and impose tremendous financial strain on the health care system, calling for new approaches to treat CVD.

The development of tools for genetic manipulation of the cardiovascular system may offer new possibilities for the treatment of cardiovascular diseases.[3-6] Gene transfer can be used as a gain of function strategy to replace or augment the function of defective or undercompensating genes that are involved in disease progression (Fig. 3–1) (for review see reference 6). Strategies for gene silencing have also been successfully used to inhibit genes that are involved in the pathogenesis of CVD (see Fig. 3–1).[6-9] Some of these strategies have progressed to early phase clinical trial testing and others are currently in advanced clinical evaluation (for review see references 6 and 10). Notwithstanding these very significant advances, the successful translation of these novel preclinical therapies into clinical practice will require the development of safe and efficient vectors and delivery tools for gene manipulation.

In this chapter, we use select examples to illustrate the therapeutic potential of these novel strategies in the treatment of common cardiovascular diseases such as coronary artery disease, heart failure, arrhythmias, and vascular diseases.

GENE THERAPIES FOR MYOCARDIAL PROTECTION

The development of gene therapies for acute myocardial infarction (AMI) is not possible with the delivery vectors currently available, because the amount of time required for transgene expression exceeds the time window for successful intervention. For this reason, gene transfer of anticoagulant genes is not feasible as treatment for AMI. The overexpression of cytoprotective genes such as those coding for antioxidant enzymes[11-18] and survival proteins[19,20] has emerged as a potential strategy for myocardial protection from ischemic injury (Table 3–1), and the inhibition of endothelial cell activation may yield some value as anti-inflammatory and immunosuppressive treatment in AMI and in cardiac transplantation[21-23] (for review see reference 24).

Gene Therapy for Protection Against Oxidative Stress-Induced Injury

Because oxidative stress plays a dominant role in myocardial injury, overexpression of antioxidant genes has been proposed as a strategy for protection of the myocardium from reactive oxygen species-induced injury[11-15, 17] (for review see reference 6). The feasibility of antioxidant enzyme gene transfer in long-term myocardial protection from ischemia and reperfusion (I/R) injury was demonstrated using adeno-associated virus (AAV) vector for intramyocardial delivery of heme oxygenase-1 (HO-1), an enzyme that is involved in the catabolism of heme. Overexpression of HO-1 several weeks in advance of

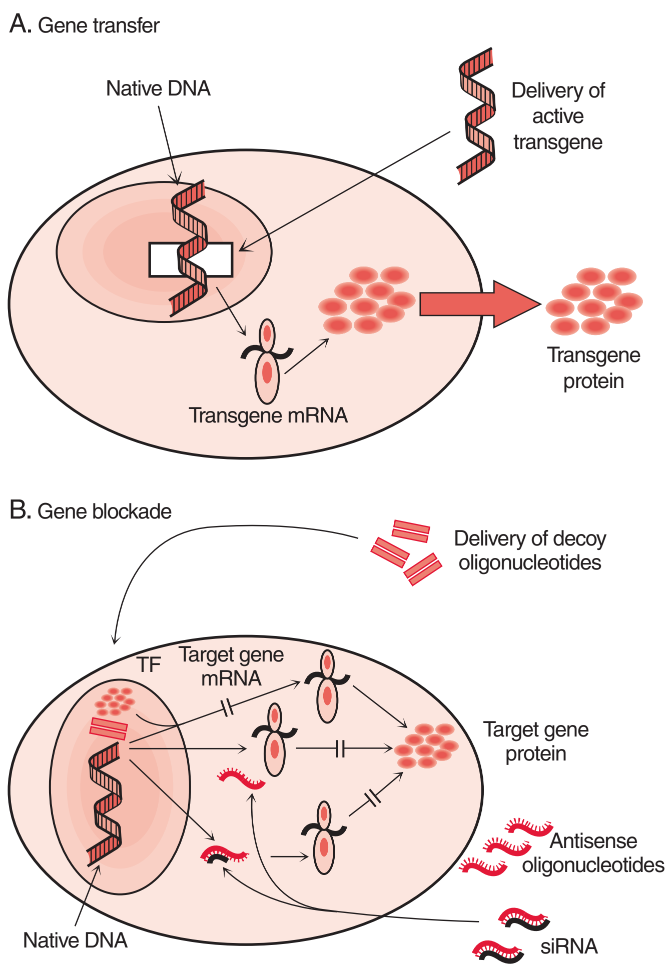

Figure 3–1 Strategies for genetic manipulation in the cardiovascular system. **A,** Gene transfer involves the delivery of exogenous genes (transgenes) by a vector capable of expressing the therapeutic protein in the host cells to increase the activity of the gene(s) (gain of function) whose endogenous function may be deficient and cause disease. **B,** Gene blockade involves inhibition of genes involved in the pathogenesis of disease. Three strategies are commonly used to inhibit gene activity at the transcriptional or translational level. Short single-stranded deoxyoligonucleotides complementary to the target gene mRNA (antisense oligonucleotides) are delivered to the target cells or tissue by transfection or with the aid of a vector. The antisense deoxyoligonucleotide binds to the target mRNA transcript and prevents it from being translated. The second strategy employs double-stranded deoxyoligonucleotides containing the consensus binding sequences (decoy oligonucleotides) for transcriptional factors involved in the activation of pathogenic genes. Transfection of a molar excess of the decoy oligonucleotide prevents the binding and transactivation of the genes regulated by the target transcriptional factor. A novel strategy uses small interfering RNAs (siRNA) to knock down the endogenous activity of pathogenic genes. Less commonly, short segments of RNA with enzymatic activity (ribozymes) are used to degrade target mRNA transcripts.

acute myocardial infarction resulted in approximately 80% reduction in infarct size in rats (Fig. 3–2).[11] The reduction in myocardial injury in the treated animals was accompanied by decreases in oxidative stress, inflammation, and interstitial fibrosis, leading to post-infarction functional recovery, normalization of left ventricular dimensions and increased long-term survival (see Fig. 3–2).[12,13] Significant protection from I/R injury has also been achieved with overexpression of other major antioxidant enzyme systems, such as ecSOD,[14] Cu/Zn SOD,[15] catalase,[15,16] glutathione peroxidase,[17] and stress-induced heat-shock proteins.[18] These findings suggest that preemptive delivery of antioxidant enzymes may be a useful strategy to potentiate endogenous antioxidant reserves for protection of myocardium at risk. Significant myocardial protection from I/R injury has also been reported with overexpression of survival genes such as Bcl-2 and Akt,[19,20] immunosuppressive cytokines[21-24] (for review see reference 25), adenosine A_1 and A_3 receptors[26] and hepatocyte growth factor.[27-29]

Gene Therapy for Myocardial Protection Against Apoptosis and Inflammation

Inhibition of pro-inflammatory genes could be a potential strategy for acute protection from I/R injury. Morishita and colleagues[8] showed that pretreatment with a decoy oligonucleotide capable of inhibiting the transactivating activity of NF-κB reduced myocardial infarct size after coronary artery ligation in rats. The inhibition of adhesion molecule expression could potentially be useful in the treatment of acute myocardial ischemia during cardiac transplantation. For example, treatment with antisense oligonucleotide directed against intercellular adhesion molecule-1 (ICAM-1) was shown to prolong cardiac allograft tolerance and long-term survival if administered ex vivo before transplantation into the host.[22] Others have shown that intracoronary delivery of the immunosuppressive genes TGF-β and interleukin-10 (IL-10) markedly reduced acute rejection and prolonged survival of heterotopically transplanted cardiac allografts,[21] whereas ex vivo intraluminal delivery of NF-κB[23] or E2F[24] decoy oligonucleotide attenuated cardiac allograft arteriopathy both in mice and nonhuman primates. These genetic strategies targeting modulation of the inflammatory and immune responses may have therapeutic potential in the treatment of myocardial infarction and in prevention of acute and chronic transplant rejection (for review see reference 25). In the first case, the inhibition of the inflammatory response in the infarcted myocardium may prevent expansion of the infarct and attenuate chamber remodeling, leading to enhanced long-term post-infarction outcome. In the case of organ transplantation, the transduction of donor organs before transplantation with a vector capable of conferring long-term local expression of immunomodulatory and antiproliferative genes would remove the need for immunosuppressive drug therapy and eliminate the problems associated with its use.

Despite the compelling pre-clinical evidence demonstrating the therapeutic potential of overexpression of cytoprotective genes in myocardial protection, the suitability and efficacy of these therapies for patients with coronary artery disease have not been evaluated. A number of issues remain regarding the feasibility, optimal method of delivery, and time

Table 3–1 Targets for Gene Therapy for Myocardial Ischemic Diseases

Disease	Therapeutic Target	Genetic Manipulation	Vector	References

Figure 3–2 (*See also Color Plate 3–2.*) Gene therapy strategy for long-term myocardial protection. The therapeutic gene (HO-1) or reporter gene (LacZ) was delivered by intramyocardial injection to the left ventricle territory supplied by the left anterior descending (LAD) coronary artery; 8 weeks later, ischemia and reperfusion (I/R) injury was induced by ligation and release of the LAD. **A** and **B,** gross (TTC) and microscopic (H&E) histological analysis of the infarcted region 24 hours after reperfusion revealed significant reduction in myocardial injury in the HO-1–treated animals compared with the untreated control animals. **C** and **D,** Marked thinning and remodeling of the anterior left ventricular free wall and interstitial fibrosis were seen 3 months after infarction in the hearts from untreated animals. However, ventricular morphology was preserved in the HO-1–treated animals in association with reduced interstitial fibrosis. **E,** Echocardiographic analysis of left ventricular function and chamber dimensions 1 month after acute myocardial infarction showed normalization of ventricular function (fractional shortening [FS] and ejection fraction [EF]) and left ventricle dimensions (left ventricular diastolic [LVDD] and systolic [LVSD] diameters) in the HO-1–treated animal. (Data modified from Melo LG, Agrawal R, Zhang L, et al: Gene therapy strategy for long-term myocardial protection using adeno-associated virus-mediated delivery of heme oxygenase gene. Circulation 2002;105:602-7 and Liu X, Pachori AS, Ward CA, et al: Heme oxygenase-1 [HO-1] inhibits postmyocardial infarct remodeling and restores left ventricular function. FASEB J 2006;20:207-16.)

pro-angiogenic genes has been reported to promote neovascularization of ischemic myocardium in several animal models and in humans with coronary artery disease[27-29,31-42] (for review see references 6, 11, 31), and genetic manipulation of calcium regulating proteins and β-adrenergic signaling was shown to improve contractile function of failing myocardium (see Table 3–1).[43,44] The use of gene therapy to correct congenital heart and vessel disease is problematic because the genes involved are developmentally regulated.[45] However, gene therapy may have potential in the treatment of some forms of inherited cardiac diseases resulting from single gene mutations, such as arrhythmias and inherited cardiomyopathies.[46-48]

Gene Transfer to Induce Therapeutic Angiogenesis

Evidence of enhanced neovascularization and functional recovery has been demonstrated in several animal models of myocardial and hind limb ischemia after delivery of pro-angiogenic growth factors (see Table 3–1).[27-29,32-35] In all cases, tissue perfusion was improved in association with histological and angiographic evidence of new vessel formation. For example, Mack and coworkers[32] showed improvements in regional myocardial perfusion and left ventricular function in response to stress after delivery of $VEGF_{121}$ in a pig model of chronic myocardial ischemia. Using a similar model, Giordano and associates[33] showed improvement in blood flow and a reduction in stress-induced functional abnormalities after intracoronary injection of human FGF-5 as early as 2 weeks after induction of ischemia, in association with an increase in capillary to fiber ratios. Similarly, intramyocardial delivery of hepatocyte growth factor (HGF) markedly improved post-infarction myocardial blood flow and left ventricular function in dogs,[29] mice,[29] rats,[28,49] and in cardiomyopathic Syrian hamsters[50] in association with enhanced neovascularization.

Despite these findings, there are several outstanding issues relating to the safety and sustainability of therapeutic angiogenesis. It is of paramount importance to put safety measures in place to avert hazardous late-onset side effects such as neovascularizaton of occult neoplasms, retinopathy, or peripheral vascular effects that may result in edema formation or hypotension. For example, Lee and colleagues[51] reported that constitutive overexpression of VEGF led to intramural angiomas followed by heart failure and death, whereas Celleti and coworkers reported that VEGF expression accelerates plaque progression.[52] A possible solution to these problems is to devise tissue-specific vectors incorporating physiologically responsive promoter elements capable of adjusting transgene expression in response to changes in tissue milieu, such as reduced oxygen and inflammation.[53,54] Another approach to achieve regulated therapeutic angiogenesis employs modified transcription factors capable of activating endogenous angiogenic gene expression in response to tissue hypoxia.[55] A novel strategy reported by Amano and colleagues[56] uses a viral vector encoding alterations in the splicing sequences of the VEGF gene to alter the normal ratio of expressed VEGF isoforms. Using this approach, these authors showed that administration of an adenovirus encoding a modification of the splicing sequences for exon 6A to favor expression of $VEGF_{189}$ at the expense of $VEGF_{121}$ led to less pulmonary edema and decreased mortality after intratracheal administration[56] than a vector encoding the three VEGF isoforms in the normal physiological ratios. Regarding the therapeutic sustainability, it will be necessary to establish whether the desired long-term therapeutic effect can be achieved with a single administration of the therapeutic gene or whether multiple treatments may be required. This is an important consideration because angiogenic factor-induced neovessels may regress after termination of transgene expression in the absence of adequate blood supply.[57,58] It is likely that the optimal strategy for therapeutic angiogenesis may require the simultaneous overexpression of multiple genes essential for growth and maturation of new vessels. Several studies are currently under way to evaluate the therapeutic benefit of multi-gene transfer in inducing neovascularization.

Gene Therapy for Rescue of Contractile Function

Rescue of contractile function in the failing myocardium is another potential target for gene therapy. The failing myocardium is characterized by alterations in calcium handling, decreased myofilament sensitivity, excessive catecholamine release, and adrenergic receptor downregulation and desensitization[59]—leading to decreased contractility. The β-AR signaling and calcium-regulating pathways have for several years been used as targets for the treatment of heart failure.[59] Contemporary studies suggest that genetic manipulation of these targets may be useful in the treatment of heart failure. Adenovirus-mediated intracoronary delivery of the β_2-AR gene led to improvements in basal and isoproterenol-stimulated LV contractility and hemodynamic function in rabbits,[60] and rescued β-AR signaling in ventricular myocytes from failing hearts.[44,61] Lai and associates demonstrated that intracoronary delivery of adenovirus expressing adenylate cyclase type VI (AC_{VI}) improved left ventricular function and reduced chamber dilatation in pigs with heart failure,[62] at least in part by restoring β-AR-stimulated cAMP generation.[63]

Gene therapy strategies for normalization of myocardial cytosolic calcium transients have also shown promising results in experimental models of heart failure (see Table 3–1) (for review see reference 43). Intracoronary SERCA2a gene delivery by adenovirus restored systolic and diastolic function concomitant with an increase in basal Ca^{2+}-ATPase activity in a rat model of heart failure induced by aortic coarctation.[64] Furthermore, SERCA2a gene transfer normalized cytosolic transients and restored contractile function in ventricular myocytes isolated from patients with end-stage heart failure.[65] Presumably, overexpression of SERCA2a restores the normal stoichiometry between phospholamban and the Ca^{2+}-ATPase, thereby preventing cytosolic calcium overload and left ventricular dysfunction. Subsequently Cittadini and colleagues[66] showed that intracoronary delivery of the serine threonine kinase Akt1 gene using adenovirus enhanced contractility in normal rats in association with increased systolic Ca^{2+} levels. However, the therapeutic usefulness of Akt as an inotropic agent for the failing heart remains unsettled because this kinase induces cardiac hypertrophy,[67] thus increasing oxygen consumption and energetic cost to perform cardiac work.

The long-term efficacy and safety of adenoviral-mediated myocardial expression of adrenergic and calcium-regulating proteins remain to be established. Sustained expression of the therapeutic transgene may be essential for rescue of the failing

heart. The physiological consequences of chronic β-AR and SERCA2a overexpression are not known. Concerns have been raised that the increase in SERCA2a expression by gene transfer in the failing heart may impose extra demands on myocardial energy expenditure owing to an increased inotropic state, and may cause adverse electrophysiological events such as arrhythmias (for review see reference 68). Such potential adverse effects could accelerate myocardial cell death and precipitate the progression of heart failure. Similarly, increased Akt activity was reported in patients with advanced heart failure,[69] and chronic Akt activation was found to markedly reduce functional recovery after myocardial infarction.[70]

Gene Therapy for Cardiac Arrhythmias

Arrhythmias can be both a cause and consequence of heart failure (for review see reference 71). Current approaches for management of arrhythmias using antiarrhythmic drugs, implantable devices, or radiofrequency ablation are limited by poor efficacy, high cost, and potential risks, indicating the need for alternative approaches for treatment of these diseases. Myocardial delivery of genes encoding defective channel proteins may provide a strategy for correction of the genetic defects associated with inherited and acquired LQT syndromes (see Table 3–1), and the ability to change myocyte electrical behavior by gene transfer has already been documented by several groups.[47,48,72-74] For example, overexpression of potassium channels could be used to reverse the occurrence of ventricular tachyarrhythmias in heart failure. In this regard, Nuss and associates[48] showed that adenoviral transfer of the human K^+ channel gene HERG to adult rabbit ventricular myocytes maintained in primary culture led to abbreviated action potentials and drastically reduced the incidence of early afterdepolarizations after a train of action potentials. This was associated with increased duration of the refractory period. The HERG gene encodes the K^+ channels mediating the faster component of the delayed rectifier potassium current (I_{Kr}) that is critical for myocardial repolarization. The pathophysiological role of K^+ channels mutations in LQT arrhythmias was further established by adenoviral transfer of mutants of the HERG and KCNE1 (I_{Ks}) into the myocardium of guinea pig.[73] Both mutant genes increased beat-to-beat variability and the incidence of early afterdepolarizations. Mutations in both genes have been found in patients with LQT.[71] These findings suggest that K^+ channels responsible for I_{Kr} and I_{Ks} may have potential as targets for gene therapy for prevention of arrhythmias caused by unstable repolarization and heritable LQT disease. Others have demonstrated a therapeutic benefit in the treatment of arrhythmia using gene transfer of G-proteins. For example, Donahue and associates[47] and Bauer and colleagues[72] were able to reduce heart rate following atrial fibrillation in pigs by local delivery of $G\alpha_{i2}$ gene to the atrioventricular node by adenovirus, suggesting that this approach may have application in the treatment of atrial arrhythmia. An alternative approach for heart failure may involve simultaneous transfer of contractility enhancing genes such as SERCA and genes involved in regulation of myocyte electrical activity, such as K^+ channels. Support for this approach was provided by Ennis and colleagues, who showed that co-expression of SERCA1 and the potassium channel Kir2.1 reduces the repolarization time without affecting contractility in guinea pig hearts,[74] suggesting that this strategy may exert synergistic effects in correcting the depressed contractility and delayed repolarization that is commonly seen in heart failure in association with potassium channel downregulation.

Gene Therapy for Inherited Heart Disease

In principle, non-lethal myocardial disease resulting from single gene mutations could be corrected by exogenous delivery of the normal gene. However, the unavailability of vectors capable of efficient long-term gene expression has been a major impediment in the design of rescue therapies for inherited heart disease. Preclinical data support the feasibility of gene therapy for some forms of inherited cardiomyopathy (see Table 3–1). Kawada and colleagues[46] showed that intramyocardial delivery of δ-sarcoglycan to 5 week-old TO-2 Syrian hamsters using an AAV vector completely rescued the progression of cardiomyopathy and markedly increased life expectancy of the treated animals. The design of gene therapies for congenital heart and vessel disease is problematic because the genes involved are developmentally regulated.[45] The ability to intervene and reprogram a defective gene within the crucial developmental time window requires the availability of diagnostic tools that would permit detection of such mutations before the onset of disease or critical developmental events, and access to an effective system for in utero gene delivery. Currently, the prohibitive cost of screening technologies for congenital diseases restricts their use in cases with a strong familial history, thereby leaving many undiagnosed cases.

GENE THERAPIES FOR VASCULAR PROTECTION

Several gene therapy strategies have been developed to reduce vascular tone, plasma cholesterol levels, and vessel wall proliferation in animal models of vascular disease (Table 3–2). The overexpression of vasodilator genes[75-78] or the inhibition of vasoconstrictor peptides[79-83] has been shown to reduce blood pressure in hypertensive animals, and the inhibition of cell cycle progression[9,84-88] or the overexpression of antiproliferative[89-93] or antioxidant[94-97] genes have emerged as useful therapeutic targets for prevention of restenosis and graft atherosclerosis (see Table 3–2). In addition, the overexpression of antithrombotic genes[98-101] and the inhibition of pro-inflammatory and cell-adhesion molecules[102] has shown therapeutic potential for the treatment of thrombosis and inflammation of the vessel wall.

Vascular Tone

Long-term reductions in vascular tone and blood pressure have been achieved in hypertensive animals with exogenous overexpression of vasodilatory genes (see Table 3–2).[75-78] For example, intravenous delivery of a plasmid encoding human endothelial NOS led to a sustained hypotensive effect in SHR rats,[75] and systemic delivery of atrial natriuretic factor,[76] adrenomedullin[77] or kallikrein[78] genes with a constitutively active adenoviral vector decreased blood pressure and attenuates renal and myocardial damage in salt-fed Dahl salt-sensitive and DOCA-salt rats. Another gene therapy strategy for hypertension involves the inhibition of pressor pathways

Table 3–2 Targets for Gene Therapy for Vascular Diseases

Strategy	Therapeutic Target	Genetic Manipulation	Vector	References
	Vasodilation			
Vascular tone	Kallikrein, eNOS, ANP, CNP, HO-1, ecSOD	Overexpression	AD, AAV	75-78
	Vasoconstriction ACE, AGT, AT_1	Inhibition	AAV-AS-ODN	79-84
Atherosclerosis	*Plaque stabilization (CAD)*			
	CD40	Overexpression	AD, AAV(?)	98, 101, 102, 107
	Cholesterol homeostasis			
	LDL-R, lipoprotein lipase, hepatic lipase, Apo-E, VLDL-R, SR-B1, Apo-A1	Overexpression	ADV	102, 108, 110
	Thromboprotection			
	PAI-1, plasminogen activator	Inhibition	AS-ODN	86, 89, 90, 93, 96, 98-101
	Tissue factor, MCP-1			
	t-PA, hirudin, urokinase	Overexpression	ADV, AAV, RV	Tissue factor pathway inhibitor
	Thrombomodulin, COX-1, PGI_2 synthase			
	eNOS, INOS, HO-1, SOD			
Vascular cell proliferation	*Cell-cycle proteins*			
	p16, p21, p27, p53, Rb	Overexpression	Plasmid, ADV, HVJ	9, 85-88
	Cdc2, cdk2, c-myb, c-myc,	Inhibition	AS-ODN,	
	PCNA, E2F,	Inhiibition	Decoy-ODN	
	Cytotoxic/suicide genes			
	Thymidine kinase	Overexpression	ADV	104
	Antiproliferative genes			
	eNOS, INOS, ecSOD, HO-1	Overexpression	ADV, AAV	90-95, 97
	TF, cytokines, apoptotic and signaling molecules			
	NF-κB, $BcL\text{-}X_L$	Inhibition	Decoy-ODN, AS-ODN	
	Fas ligand, Gax, GATA-6	Overexpression	ADV	
	β-interferon, VEGF			

AAV, adeno-associated virus; ACE, angiotensin-converting enzyme; ADV, adenovirus; AGT, angiotensinogen; AT1, angiotensin II-type 1 receptor; ANP, atrial natriuretic peptide; AS-ODN, antisense oligodeoxynucleotide; CAD, coronary artery disease; CNP, C-type natriuretic peptide; COX-1, cyclooxygenase-1; eNOS, endothelial nitric oxide synthase; HF, heart failure; HO-1, heme oxygenase-1; iNOS, inducible nitric oxide synthase; NF-κB, nuclear factor kappa B; PCNA, proliferating cell nuclear antigen; PGI2 synthase, prostacyclin synthase; PAI-1, plasminogen activator inhibitor-1; RV, retrovirus, SOD, superoxide dismutase; TPA, tissue plasminogen activator; VEGF, vascular endothelial growth factor.

using antisense oligonucleotides against components of the renin-angiotensin system (RAS)[79-82] or the β-adrenergic signaling pathway.[83] Using AAV for intravenous delivery of angiotensinogen antisense cDNA, Tang and coworkers[79] showed a dose-dependent decrease in arterial blood pressure in spontaneously hypertensive adult rats (SHR) in association with reduced angiotensinogen levels, and Kimura and coworkers[80] reported that the onset of hypertension was delayed up to 6 months in SHR after a single intracardiac injection of angiotensinogen antisense cDNA in newborn SHR rats. Comparable results were reported with antisense inhibition of angiotensin converting enzyme[81] or AT_1 receptor.[82] Sustained reduction in blood pressure has also been achieved by antisense inhibition of β_1-adrenergic receptor,[83] suggesting that this strategy could be used as an alternative to pharmacological β-blockade.

The therapeutic efficacy of antihypertensive gene therapy has not been assessed in humans despite its simplicity, safety, and apparent efficacy. Enthusiasm for these novel approaches is moderated by the clinical efficacy of current antihypertensive drugs. Nevertheless, the prospect of achieving long-term control of blood pressure in hypertensive patients by gene therapy is an attractive feature that could overcome the problem with compliance often manifested by patients on antihypertensive drugs.

Neointima Proliferation

Percutaneous coronary intervention (PCI), and coronary artery bypass grafting (CABG) are the current treatment options for patients with coronary artery disease requiring revascularization. However, the failure rate of these proce-

dures owing to restenosis and atherosclerosis remains relatively high, despite the introduction of novel drug-eluting stents. The ability to inhibit proliferation of the medial smooth muscle using gene therapy techniques provides the opportunity to genetically engineer native vessels and grafts to render them resistant to atherosclerosis and neointimal hyperplasia (for review see references 84, 103).

Two anti-restenosis gene therapy strategies have been used to inhibit neointimal hyperplasia, using a wide variety of therapeutic targets. Cytostatic strategies involve the inhibition of key proteins regulating cell cycle progression to arrest neointimal cell proliferation (see Table 3–2).[85-88] We used this strategy to treat jugular veins in vivo with hemagglutinating virus of Japan (HVJ)-liposome complexes containing antisense oligonucleotide against cell-cycle regulators proliferating cell nuclear antigen (PCNA) and cdc2 kinase in atherosclerotic New Zealand rabbits before carotid artery interpositional grafting.[87] The gene therapy led to adaptive remodeling of the graft, successfully inducing medial hypertrophy while inhibiting neointimal hyperplasia, to yield conduits that resemble normal arteries.[88] Subsequent histological and functional analyses of the treated vein graft showed marked inhibition of graft atherosclerosis, decreased inflammation, and improved endothelial function (Fig. 3–3).[88] Subsequently, it was reported that the treatment of vein grafts before implantation with a decoy deoxyoligonucelotide bearing the consensus binding sequence of E2F-1, a transcriptional factor involved in cell-cycle progression, resulted in prolonged resistance to neointimal hyperplasia and improved patency of the graft after transplantation.[9] An interesting variant in cytostatic gene therapy involves the targeted expression of the thymidine kinase gene. The gene renders the transduced cells sensitive to antiviral drugs such as ganciclovir, such that treatment with the drugs eradicates the vector targeted cells. This strategy, commonly known as *suicide gene therapy,* has been used successfully to reduce neointima proliferation in atheromatous iliac arteries from rabbits.[104]

Delivery of antiproliferative genes such as those coding for the nitric oxide synthases offers another approach to achieve inhibition of neointimal hyperplasia (see Table 3–2). All three isoforms of nitric oxide have been shown to exert vasculoprotective and antiproliferative effects after gene transfer (for review see reference 89). Endothelial and iNOS gene transfer are equally efficacious in reducing neointimal thickening in balloon-injured vessels.[90-93] Local delivery of antioxidant enzymes such as HO-1[94,95] and ecSOD[96,97] by adenovirus has also been shown to inhibit neointima hyperplasia in various animal models of restenosis, possibly owing to reduction in inflammation and oxidative stress during the early phase of vascular injury.

Atherosclerosis and Thrombosis

Plaque rupture and subsequent thrombosis and occlusion are the major causes of acute coronary episodes that result in myocardial infarction and sudden cardiac death.[105,106] Gene therapy aimed at reducing the cholesterol level and/or at increasing thromboresistance and tensile strength within the plaque could potentially offer the possibility to achieve long-term plaque stabilization and prevent the occurrence of acute coronary events (see Table 3–2).[107] For example, the over expression of apoprotein ApoA-1 in mice by intravenous adenoviral gene delivery increases serum HDL levels,[108] whereas the blockade of monocyte infiltration and activation in the arterial

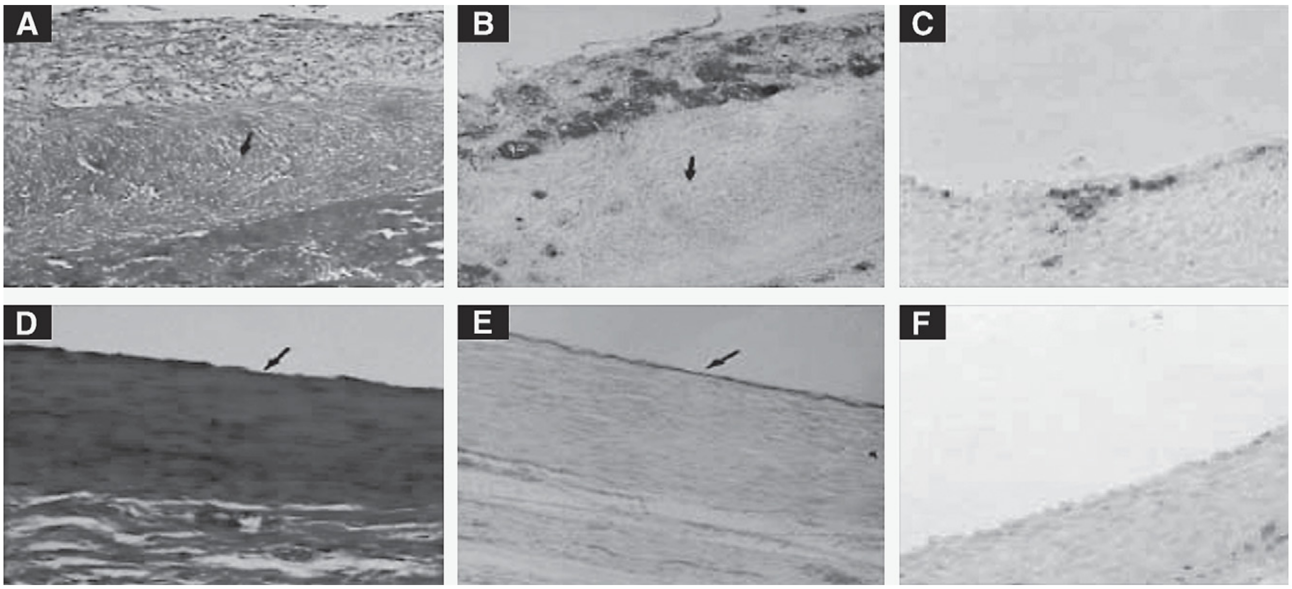

Figure 3–3 (*See also Color Plate 3–3.*) Intraoperative genetic engineering of atherosclerosis-resistant vein grafts by selective inhibition of cell cycle regulatory genes cdc2 kinase and proliferating cell nuclear antigen (PCNA) using antisense deoxyoligonucleotides. **A-C,** Jugular vein grafts from hypercholesterolemic rabbits 6 weeks after carotid inter-positional grafting showed significant neointima hyperplasia (**A**), infiltration of foam cells throughout the intima and subendothelial regions (**B**), and increased adhesion molecule (VCAM-1) expression (**C**). **D-F,** Selective blockade of cdc2 kinase and PCNA in hypercholesterolemic rabbits leads to inhibition of neointimal deposition (**D**), significantly reduced foam cell accumulation and plaque formation (**E**) and inhibition of adhesion molecule (VCAM-1) expression (**F**).

continued

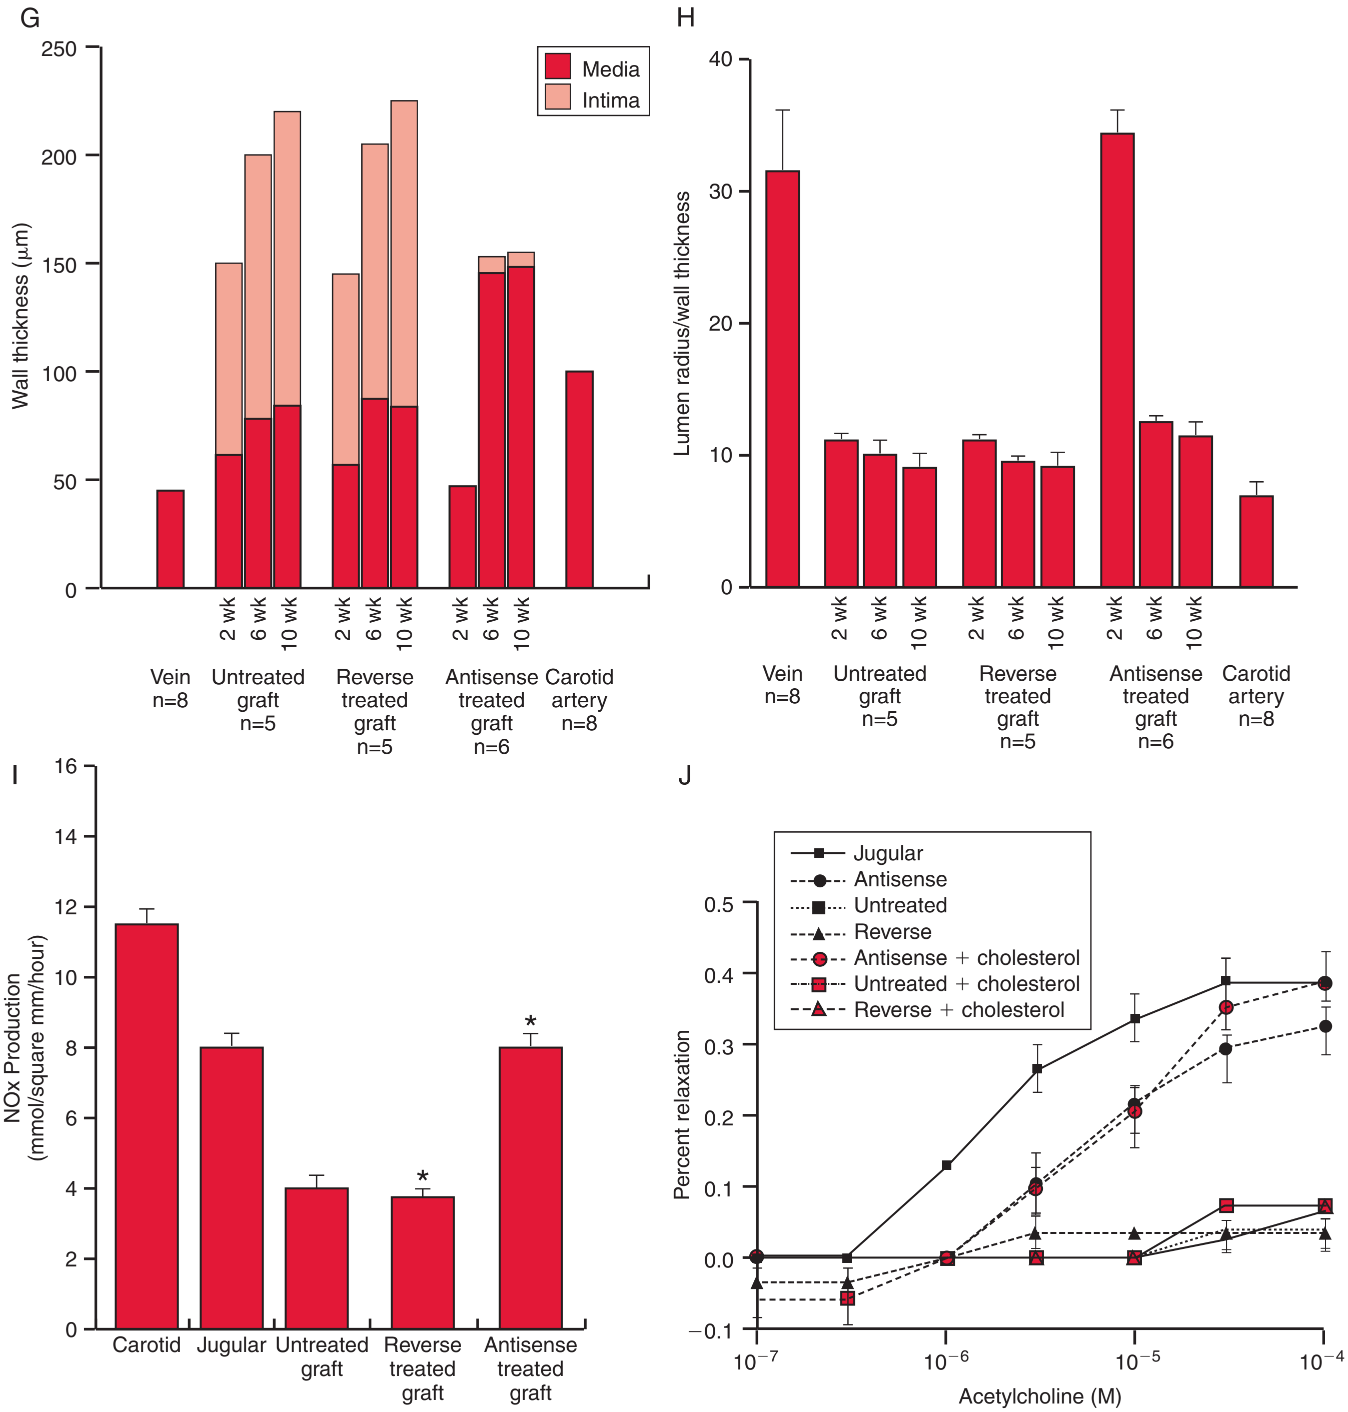

Figure 3–3, cont'd **G-H,** Inhibition of cdc2 and PCNA with the antisense oligonucleotides promoted positive remodeling of the vein graft characterized by increased media hypertrophy and reduced neointima hyperplasia to yield fully arterialized conduits. **I-J,** Treatment of the vein grafts with the antisense deoxyoligonucleotide resulted in increased nitric oxide production (**I**) and improved endothelial function (**J**). (Data modified from Mann MJ, Gibbons GH, Kernoff RS, et al: Genetic engineering of vein grafts resistant to atherosclerosis. Proc Natl Acad Sci U S A 1995;92[10]:4502-6 and Mann MJ, Gibbons GH, Tsao PS, et al: Cell cycle inhibition preserves endothelial function in genetically engineered rabbit vein grafts. J Clin Invest 1997;99[6]:1295-301.)

wall by inhibition of monocyte chemoattractant protein-1 (MCP-1) receptor activation was shown to retard the onset of atheroma and to limit progression and destabilization of established atherosclerotic lesions in ApoE deficient mice.[102] Another important target for vascular protection is eNOS (for review see reference 89). Endothelium-derived NO exerts a plethora of vasculoprotective actions, including vasorelaxation, inhibition of VSMC proliferation and migration, and inhibition of platelet activation and adhesion.[109] NOS gene transfer provides a mechanism to increase NO bioac-

tivity and enhance the antiatherogenic properties of the vessel wall. For example, gene transfer of eNOS reduces inflammatory cell infiltration and lipid deposition in carotid arteries of cholesterol-fed rabbits.[93] Gene transfer of cytoprotective genes such as HO-1 and SOD has also been shown to exert vasculoprotective effects. Adenovirus-mediated delivery of HO-1 attenuated the development of aortic lesions in ApoE-deficient mice, in parallel with a decrease in iron deposition,[95] and delivery of manganese superoxide dismutase gene improved vascular function in pre-atherosclerotic carotid arteries from hypercholesterolemic rabbits.[96]

Lipid-lowering gene therapy may be useful in the treatment of inherited disorders of lipid metabolism such as familial homozygotic hypercholesterolemia (FHH) and apoE deficiency because of their refractoriness to medical treatment. For these patients, gene therapy may offer hope for a cure because of the monogenic nature of these diseases. The use of lipid-lowering gene therapy in patients with FHH has, to date, been evaluated only in a small phase I feasibility clinical trial.[110] Three out of five patients treated with a retroviral vector expressing the wild-type LDL receptor showed a reduction of 6% to 23% in plasma LDL levels, but the duration of gene expression was short, possibly due to endogenous retroviral silencing. The development of clinically effective therapies for FHH and apoE deficiency will be dependent on the availability of vectors capable of providing stable, long-term expression of the therapeutic gene. This will require a vector capable of chromosomal integration without triggering insertional mutagenesis. Furthermore, the need for long-term therapeutic gene expression will require tissue-specific regulated expression of the transgene to avert potential cytotoxic effects of transgene expression. One potential strategy is to use a physiologically-regulated AAV vector for skeletal muscle or liver-specific expression of ApoE or the LDL receptor (for review on regulatable vector systems see reference 111).

CLINICAL GENE THERAPY

Despite the compelling pre-clinical evidence about the feasibility and efficacy of gene therapy in the treatment of cardiovascular diseases, only a few small-scale trials have been carried out.[112] Of the 918 trials that have been finished or currently under way worldwide, only 8.3% are in cardiovascular disease. The majority of these trials evaluated the therapeutic efficacy of angiogenic gene transfer in the treatment of coronary and peripheral ischemia (Table 3–3)[36-38, 41, 113-128](for review see references 112, 129). Although the trials generally support the feasibility and safety of angiogenic gene transfer, the clinical findings have been inconclusive with regard to the efficacy of angiogenesis gene therapy. In a phase I study in five male patients 53 to 71 years of age with CAD who did not respond to conventional anti-angina therapy, intramyocardial delivery of naked plasmid encoding $VEGF_{165}$ into the ischemic

myocardium led to reduction of anginal symptoms and improvement, albeit modest, in left ventricular function concomitant with reduced ischemia.[38] Vale and colleagues[39] reported significant reductions in weekly anginal attacks and reduced nitroglycerin consumption in six patients with chronic myocardial ischemia for as long as 1 year after catheter-based delivery of naked VEGF-2 (VEGF-C) assisted by electromechanical NOGA mapping of the left ventricle. SPECT-sestamibi scanning of these patients showed improved myocardial perfusion for up to 90 days in the patients treated with the gene. These authors have subsequently completed a phase 1/2 placebo-controlled, double-blind, dose-escalating trial using the same NOGA-assisted catheter-based delivery of VEGF-2 in 19 no-option patients (average age, 61 years) with Canadian Cardiovascular Society class III or IV angina.[40] Endpoint analysis at 12 weeks after treatment showed an improvement in anginal symptoms with reduced ischemic area and increased exercise tolerance in the patients treated with the VEGF-2 gene, whereas no improvement was seen in the placebo control patients.[40] Similar results were reported for the EUROINJECT-ONE trial.[113] In this phase II randomized double-blind trial, 80 no-option patients were treated by intramyocardial injection of a plasmid-encoding human VEGF-A_{165} (ph VEGF-A_{165}) ($n = 40$) or placebo plasmid ($n = 40$) using the NOGA mapping system to deliver the plasmid to the area showing stress-induced perfusion defects. Three months after plasmid delivery, no improvement in stress-induced perfusion defects was seen in the VEGF-A_{165}-treated patients compared with the patients receiving the placebo.[113] However, the VEGF-A_{165}-treated patients showed improved regional wall motion as assessed by NOGA and contrast ventriculography.[113,114]

Another randomized, placebo-controlled, double-blind phase II trial, the Kuopio Angiogenesis trial (KAT), evaluated the safety and feasibility of catheter-based intramyocardial delivery of Ad-$hVEGF_{165}$ or $hVEGF_{165}$-liposomes in patients (mean age 58 ± 6 years) with CCS classes II and III angina undergoing percutaneous coronary angioplasty (PCA) and stenting.[115] Follow-up at 6 months did not show any significant differences in the rate of restenosis among the two $hVEGF_{165}$ groups of patients and the placebo controls. However, myocardial perfusion was slightly (6%) but significantly increased in the Ad-$hVEGF_{165}$ treated patients[115] compared with pre-treatment values, suggesting that intracoronary delivery of angiogenic cytokines at the time of PCA may be a useful adjuvant therapeutic strategy to enhance coronary perfusion in patients with coronary artery disease undergoing surgical revascularization. Interestingly, despite the decrease in perfusion defect score, no significant improvement was seen in exercise time and rate pressure product in the Ad-$hVEGF_{165}$-treated patients.

Gene transfer of other angiogenic cytokines, such as fibroblast growth factor (FGF), has also been evaluated for treatment of ischemic heart disease. The Angiogenic GENe Therapy (AGENT), a phase I/II double-blind, randomized, placebo-controlled trial examined the effect of dose-escalating adenovirus-mediated intracoronary delivery of FGF-4 in 79 patients (mean age, 65 years) with CCS class II and III stable angina.[116] The results of this trial showed a general trend toward an increase in exercise tolerance and improved stress echocardiograms at 4 and 12 weeks after gene transfer in the patients treated with FGF-4 gene therapy compared with the patients receiving placebo, in association with angiographic evidence of neovascularization.[116] However, the trial was not sufficiently powered to detect statistically significant differences between the treated and placebo groups in the treadmill exercise time to fatigue, and the outcome beyond 12 weeks has not been reported for these patients. Nevertheless, the trial showed that the therapy was safe and well tolerated. Subsequently, the results of the AGENT 2 study were reported by the same group.[117] The trial assessed the effect of intracoronary AdFGF-4 gene transfer or placebo on myocardial perfusion in 52 patients (mean age, 58 years) with stable angina 8 weeks after gene transfer. Using stress-related reversible perfusion defect size (RPDS) as the primary endpoint, the results of this trial showed a decrease in RPDS and improved perfusion in the AdFGF-4-treated group ($n = 35$) compared with the placebo group ($n = 17$), but the difference did not reach statistical significance, presumably owing to the confounding effect of an outlier in the placebo group. In addition, no significant differences between the two groups were found in angina parameters (Canadian Cardiovascular Society angina class); however, a greater number of patients in the AdFGF-4-treated group reported complete resolution of anginal symptoms and no nitroglycerin use.[117] Subsequently, the AGENT 3 and 4 trials have been carried out. The AGENT 3 trial completed enrollment and follow-up of several hundred patients, but no differences were found between the AdFGF-4 and placebo-treated patients in all the primary and secondary endpoints. The AGENT 4 trial was subsequently cancelled on release of the AGENT 3 results (unpublished, for discussion on AGENT trials, please see lecture by Patrick Serruys at the 69th scientific session of the Japanese Circulation Society).

Some trials have also been undertaken to evaluate the effect of cell cycle inhibition on neointima proliferation and vein graft failure. A phase I prospective, randomized double-blind trial of human saphenous vein graft treatment with E2F decoy (Project In Ex-Vivo Vein Graft Engineering Via Transfection, PREVENT-1) was carried out in high-risk patients suffering from peripheral arterial occlusive disease.[118] Using nondistending pressure to deliver the E2F decoy oligonucleotide ex vivo before arterial interpositional grafting, we demonstrated that E2F decoy treatment was safe and feasible. Although the results were preliminary, the study provided evidence that cytostatic gene therapy is feasible for clinical application. Subsequently, PREVENT II has largely confirmed the finding of the PREVENT I trial. PREVENT II was a randomized double-blind, placebo-controlled phase II trial designed to evaluate the effect of E2F decoy treatment on CABG failure in 202 patients (one half was treated with E2F decoy) undergoing bypass surgery for at least two vessels.[119] The interim results confirmed the feasibility and safety of E2F-1 decoy. Analysis of the secondary endpoints using quantitative coronary angiography and 3-dimensional intravascular ultrasound demonstrated increased patency and adaptive vessel remodeling characterized by reduction in neointimal size and volume in the treated group 1 year after treatment, leading to a 40% reduction in critical stenosis. The results of the PREVENT IV trial have been published.[120] This phase III, multicenter, randomized double-blind, placebo-controlled trial evaluated the therapeutic efficacy of ex vivo treatment of autologous vein grafts with E2F decoy (Edifoligide) in 3014 patients from 107 sites undergoing CABG. The primary endpoint evaluated was vein graft failure, defined as death or

>75% stenosis in treated vein grafts at 12 to 18 month angiographic follow-up. The results showed that Edifoligide was no more effective than placebo in preventing graft failure 12 to 18 months after CABG surgery,[120] and the authors concluded that a longer follow-up period will be necessary to determine whether treatment with the E2F decoy has delayed beneficial effects to improve the durability of CABG surgery.

A number of early phase clinical trials of angiogenic gene therapy have also been carried out in patients suffering from peripheral artery disease.[121-128] Intra-arterial delivery of $phVEGF_{165}$ to a group of 62 patients with critical limb ischemia and 28 patients with intermittent claudication led to indices of enhanced collateral vessel development, including increased ankle-brachial and toe-brachial index, improvement of ischemic gangrene, and disappearance of ischemic rest pain. However, 34% of the treated patients also presented with lower-extremity edema, likely due to the effects of VEGF in increasing vascular permeability.[121] Subsequently, Makinen and colleagues[122] reported the results of a phase II randomized, placebo-controlled, double-blind study in which 35 patients with chronic lower limb ischemia were treated by catheter-based delivery Ad-$hVEGF_{165}$ (n = 18) or $hVEGF_{165}$-liposome (n = 17) at time of percutaneous transluminal angioplasty. Three months after gene delivery, digital subtraction angiography revealed increased vascularity distal to the site of gene delivery in both treated groups compared with the control group (n = 19) receiving Ringer's lactate. However, the ankle brachial index did not differ between the groups.[122] In another phase II dose-finding multicenter trial (RAVE, Regional Angiogenesis with Vascular Growth Factor), the authors treated 105 patients (n = 35-36 patients per group) with severe intermittent claudication by intramuscular injection of Ad-$VEGF_{121}$ at twenty sites in the muscles of the lower leg requiring revascularization, and then evaluated the change in peak walking time at 12 weeks as the primary endpoint.[123-126] The results of the RAVE trial were negative and did not yield significant differences between the Ad-$VEGF_{121}$-treated patients and the control patients in peak walking time, ankle-brachial index, claudication onset time, and quality of life measures,[126] thus failing to provide support that local delivery of a single dose of Ad-$VEGF_{121}$ may be useful in the treatment of patients with unilateral peripheral artery disease. Subsequently, Morishita and associates[127] reported the results of a small safety and feasibility trial using intramuscular injection of hepatocyte growth factor (HGF) plasmid in six patients with critical limb ischemia. No adverse effects were reported in association with the gene therapy and no peripheral edema was observed. The authors reported that the diameter of 8 out of 11 ischemic ulcers in 4 patients was reduced by >25%. These results, although preliminary, suggest that HGF gene transfer may have therapeutic potential in the treatment of peripheral artery disease and warrant larger, controlled trials.

The ability to induce therapeutic neovascularization by gene transfer has, so far, been disappointing. The success of clinical gene therapy will ultimately be determined by the ability to resolve the outstanding issues regarding safety and efficacy. Larger and more adequately controlled multicenter trials are warranted. Stringent criteria need to be applied in the selection of patients. For example, candidates for therapeutic angiogenesis often have an impaired angiogenic response because of underlying endothelial dysfunction.[58] In addition, objective endpoints for assessing efficacy need to be standardized and implemented, as well as measures to assess and overcome potential short- and long-term complications, such as edema, hypotension, retinopathy, and neovascularization of occult neoplasms. The issues surrounding therapeutic patency and sustainability of neovessels have not been adequately addressed. The ideal gene therapy strategy for therapeutic angiogenesis will likely require the simultaneous expression of multiple genes involved in the various steps of vessel development, growth, and maturation. Furthermore, the choice of vector for gene delivery needs to be carefully considered. Ideally, expression of the therapeutic genes should be subject to physiological regulation and the vector should be able to express the pro-angiogenic genes on demand in response to underlying pathophysiological changes such as tissue hypoxia. Sustainability of the therapeutic effect is another important consideration that is often ignored in the design of clinical trials. All trials, to date, have employed a single administration of the therapeutic gene. However, in all cases, the vectors used (plasmid, adenovirus) express the therapeutic genes only transiently. This may, at least in part, account for the relative lack of success in the trials completed to date. Indeed, evidence from animal studies indicates that angiogenesis is confined to the transient period of transgene expression,[57] and neovessels tend to regress after transgene expression ceases.[58] Thus, successful gene therapy for ischemic diseases may require the use of vectors capable of long-term transgene expression such as AAV, or, at the least, may require multiple treatments. The use of gene therapy for vasculoproliferative diseases also must overcome efficacy issues. The complexity of the pathological process involved in restenosis suggests that genetic manipulation of multiple targets may be necessary for effective and sustained therapeutic benefit. Strategies to accelerate endothelial recovery should also be considered because endothelial damage plays a pivotal role in the subsequent development of restenosis and graft atherosclerosis.

PERSPECTIVES AND FUTURE DIRECTIONS

In the last decade, cardiovascular gene therapy has moved beyond the "proof of concept," into the clinical arena. However, the results from cardiovascular gene therapy trials for tissue ischemia and vessel disease have been disappointing and there is urgent need for further developments in vector and delivery technologies with improved safety and efficacy profiles. The onus is in the development of efficient and nonimmunogenic vector systems capable of conferring tissue-specific expression of therapeutic transgenes in a physiologically regulated fashion. These developments are essential to avert potential ethical and biological hazards such as germ cell line transmission that could arise as a result of nonspecific transgene expression. New delivery devices, together with the new mapping techniques, should also improve the specificity of gene delivery to the areas of interest and minimize systemic spillover. There is a pressing need to define and standardize the protocols for gene transfer in clinical trials. It is also likely that the efficacy of gene therapy for CVD will be enhanced by novel strategies that will allow the simultaneous manipulation of multiple gene targets. We will likely also see an increased reliance on cell-based gene therapy combination strategies for

the treatment of diseases such as coronary artery disease and hind limb ischemia. The field of gene therapy will benefit from developments in genomic research. We envision that genomic profiling will eventually be used for screening and genotyping of patients to detect disease-causing mutations and polymorphisms that should allow the design of individualized genetic therapies.

Stem Cell Therapy for Cardiovascular Disorders

Kai C. Wollert and Helmut Drexler

The dogma of the heart as an organ composed of terminally-differentiated myocytes incapable of regeneration is being challenged. Evidence has been presented that a fraction of cardiomyocytes is able to reenter the cell-cycle and that limited regeneration can occur after tissue injury through the recruitment of resident and cardiac stem cells.[1] Another idea that has created some excitement is the concept of adult stem cell plasticity.[2,3] Stem cells are capable of self renewal, transformation into dedicated progenitor cells, and differentiation into specialized progeny. Traditionally, adult stem cells were believed to differentiate into progeny only within tissue lineage boundaries (e.g., hematopoietic stem cells giving rise to mature hematopoietic cells). Plasticity implies that stem cells can transdifferentiate into cell types outside their original lineage. In this regard, it has been reported that hematopoietic stem cells, when transplanted into infarcted mouse myocardium, transdifferentiate into cardiomyocytes and vascular cells.[4]

Current cardiovascular therapies are aimed at preventing cell damage and/or progressive functional deterioration after injury. The alleged transdifferentiation capacity of adult stem cells and the discovery of endogenous cardiac repair mechanisms have suggested, for the first time, that cardiac repair might be achieved in the clinical setting.[5] Ironically, although these new ideas have already triggered clinical trials, fusion of transplanted stem cells with resident cardiomyocytes has been offered as an alternative explanation for previous claims of transdifferentiation.[6-9] It has been proposed that stem cells secrete cytokines and growth factors that may promote angiogenesis, suppress cell death of resident cardiomyocytes, or recruit cardiac stem cells (Fig. 3–4).[10-12] Regardless of the mechanisms, there appears to be general agreement that stem cell therapy has the potential to improve perfusion and the contractile performance of the injured heart.[13]

POTENTIAL DONOR CELLS

Conceptually, a variety of stem and progenitor cell populations could be used for cardiac repair. Each cell type has its own profile of advantages, limitations, and practicability issues in specific clinical settings. Studies comparing the regenerative capacity of distinct cell populations are scarce. Many investigators have, therefore, chosen a pragmatic approach by using unfractionated bone marrow cells, which contain different stem and progenitor cell populations, including hematopoietic stem cells, endothelial progenitor cells, and mesenchymal stem cells.

Endothelial Progenitor Cells

Endothelial progenitor cells (EPC) have been defined by their cell surface expression of the hematopoietic marker proteins CD133 and CD34 and the endothelial marker vascular endothelial growth factor receptor-2, and their capacity to incorporate into sites of neovascularization and to differentiate into endothelial cells in situ. The cell surface antigen

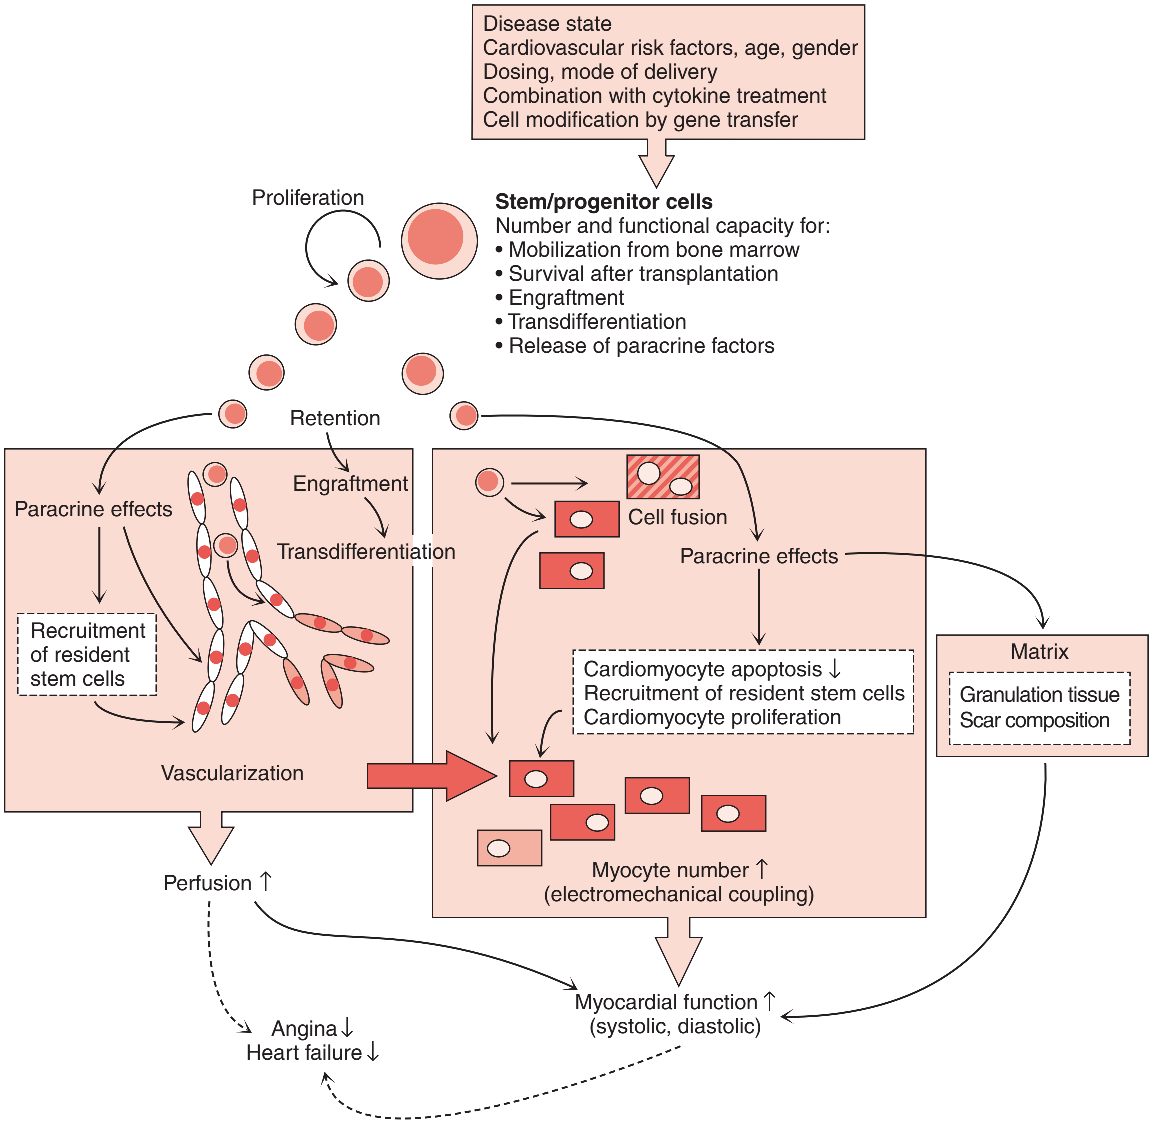

Figure 3–4 Working hypothesis of therapeutic stem cell transplantation for myocardial regeneration. Stem and progenitor cell transplantation can have a favorable impact on tissue perfusion and contractile performance by promoting vascularization and myocyte formation. Improved vascularization may facilitate beneficial effects in the myocyte compartment. Depending on the stem cell type and local milieu, the relative contribution of cell incorporation (transdifferentiation and/or fusion) versus paracrine effects may vary. Stem and progenitor cell numbers and functional capacity are influenced by a patient's age, gender, cardiovascular risk factors, and underlying disease state. (From Wollert KC, Drexler H: Clinical applications of stem cells for the heart. Circ Res 2005;96:151-63.)

CD133 is expressed on early hematopoietic stem cells and endothelial progenitor cells, both of which collaborate to promote vascularization of ischemic tissues. Increasing evidence suggests that culture-expanded EPCs also contain a $CD14^+/CD34^-/CD133^-$-mononuclear cell population with "EPC-capacity," which mediates its angiogenic effects by releasing paracrine factors.[14]

Mesenchymal Stem Cells

Mesenchymal stem cells represent a rare population of $CD34^-$ and $CD133^-$ cells present in bone marrow stroma (10-fold less abundant than hematopoietic stem cells) and other mesenchymal tissues.[15] Mesenchymal stem cells can differentiate into osteocytes, chondrocytes, adipocytes, and cardiomyocyte-like cells under specific culture conditions. When injected into infarct tissue, mesenchymal stem cells may enhance regional wall motion and prevent adverse remodeling.[16,17] It has been suggested that these effects may be related to paracrine effects rather than differentiation of mesenchymal stem cells into cardiomyocytes.[17,18] Because mesenchymal stem cells can be expanded in vitro, and reportedly have a low immunogenicity, they might be used in an allogeneic setting in the future.[15]

Skeletal Myoblasts

Skeletal myoblasts (satellite cells) are progenitor cells that normally lie in a quiescent state under the basal membrane

of mature muscular fibers. Myoblasts can be isolated from skeletal muscle biopsies and expanded in vitro. Myoblasts differentiate into myotubes and retain skeletal muscle properties when transplanted into an infarct scar. Although grafted myotubes may contract in response to electrical stimulation, they do not express intercalated disk proteins, indicating that the majority are not electromechanically coupled to their host cardiomyocytes.[19] Nevertheless, myoblast transplantation has been shown to augment systolic and diastolic performance in animal models of MI, possibly through the release of paracrine factors.[20]

Resident Cardiac Stem Cells

Several groups have detected stem and progenitor cells within the heart that are capable of differentiating into cardiomyocytes and/or vascular lineages. It has been suggested that these cells could be clonally expanded and be used for cardiac repair in an autologous setting.[21-25] Intriguingly, different groups have used distinct surface markers to characterize resident cardiac stem cells, although it is not clear yet whether this reflects the presence of distinct stem cell populations or only different stages in the evolution of a common cell type. In any case, cardiac resident stem and progenitor cells hold great promise for clinical applications, although, it is conceivable that the bone marrow may contain a cardiogenic, pluripotent stem cell population with similar properties.[26,27]

Embryonic Stem Cells

Embryonic stem cells are totipotent stem cells derived from the inner cell mass of blastocysts. Under specific culture conditions, embryonic stem cells differentiate into multicellular embryoid bodies that contain differentiated cells from all three germ layers including cardiomyocytes. Human embryonic stem cell–derived cardiomyocytes display structural and functional properties of early-stage cardiomyocytes that couple with host cardiomyocytes when transplanted into normal or infarcted myocardium.[28,29] In theory, infinite numbers of cardiomyocytes could be obtained from human embryonic stem cell clones. However, unresolved ethical and legal issues, concerns about the tumorigenicity of the cells, and the need to use allogeneic cells for transplantation currently hamper their use in clinical studies. Eventually, nuclear transfer techniques may provide a means for generating an unlimited supply of histocompatible embryonic stem cells for the treatment of cardiac disease (therapeutic cloning).

MODES OF CELL DELIVERY

The goal of any cell delivery strategy is to transplant sufficient numbers of cells into the myocardial region of interest and to achieve maximum retention of cells within that area. Retention may be defined as the fraction of transplanted cells retained in the myocardium for a short period of time (hours). The local milieu is an important determinant of cell retention because it will influence short-term cell survival and, if a transvascular approach is used, cell adhesion, transmigration through the vascular wall, and tissue invasion.

Transvascular Approaches

Transvascular strategies are especially suited for the treatment of recently infarcted and reperfused myocardium when chemoattractants are highly expressed.[30]

Intracoronary Artery Infusion

Selective intracoronary application delivers a maximum concentration of cells homogeneously to the site of injury. Unselected bone marrow cells, circulating blood-derived progenitors cells, and mesenchymal stem cells have been delivered via the intracoronary route in patients with acute myocardial infarction (AMI) and ischemic cardiomyopathy. In these studies, cells were delivered through the central lumen of an over-the-wire balloon catheter during transient balloon inflations to maximize the contact time of the cells with the microcirculation of the infarct-related artery.[31]

Intravenous Infusion

In experimental models, intravenous delivery of endothelial progenitors cells and mesenchymal stem cells has been shown to improve cardiac function after AMI. However, cell homing to noncardiac organs limits the applicability of this approach.[32,33] Indeed, in a clinical study, homing of unselected bone marrow cells to the infarct region was observed only after intracoronary stop-flow delivery but not after intravenous infusion.[34]

Mobilization of Stem and Progenitor Cells

Considering that the acutely infarcted myocardium recruits circulating stem and progenitor cells to the site of injury, mobilization of stem and progenitor cells by cytokines may offer a noninvasive strategy for cardiac regeneration. Indeed, it has been reported that the stem cell mobilizing cytokine stem cell factor (SCF) and granulocyte colony-stimulating factor (G-CSF) improve cardiac function after AMI in mice.[35,36] Notably, G-CSF can accelerate infarct healing by enhancing macrophage infiltration and matrix metalloproteinase activation and suppressing cardiomyocyte apoptosis by activating the cytoprotective STAT3 transcription factor, suggesting that stem cell independent mechanisms may contribute to the favorable effects of G-CSF post-AMI.[37,38]

Direct Injection in the Ventricular Wall

Direct injection is the preferred route for cell delivery in patients who present late in the disease process, when an occluded coronary artery precludes transvascular cell delivery (patients with chronic myocardial ischemia) or when cell homing signals are expressed at low levels in the heart (scar tissue). However, direct injection of cells into ischemic or scarred myocardium may create islands of cells with limited blood supply and lead to poor cell survival. Direct injection techniques are especially suited for the application of large cells, such as mesenchymal stem cells or myoblasts that may

cause microembolization after intracoronary delivery. Cell delivery by direct injection may not be safe in patients with a recent MI, particularly if cells are to be injected into the friable necrotic tissue.

Transepicardial Injection

Transepicardial cell injection has been performed as an adjunct to coronary artery bypass grafting. Transepicardial cell injection during open heart surgery allows for a direct visualization of the myocardium and a targeted application of cells. The invasiveness of this approach hampers its use as a stand-alone therapy. Conversely, the efficiency of cell transplantation may be difficult to ascertain if bypass grafting is performed simultaneously.

Transendocardial Injection

Using an injection needle catheter advanced across the aortic valve and positioned against the endocardial surface, cells can be directly injected into the left ventricular wall.[39] Electromechanical mapping of the endocardial surface can be used to delineate viable, ischemic, and scarred myocardium before cell injections.

Transcoronary Vein Injection

A catheter system incorporating an ultrasound tip for guidance and an extendable needle for myocardial access can be used to deliver cells through the coronary veins into the myocardium.[40] In contrast to the transendocardial approach, where cells are injected perpendicular to the ventricular wall, the composite catheter system delivers cells parallel to the ventricular wall and deep into the injured myocardium. However, positioning of the injection catheter in a specific coronary vein is not trivial in all cases.

CLINICAL APPLICATIONS OF STEM CELL THERAPY

Myocardial Infarction

Modern reperfusion strategies and advances in pharmacological management have resulted in an increasing proportion of MI survivors who are at heightened risk of developing adverse left ventricular remodeling and heart failure. None of our current therapies addresses the underlying cause of the remodeling process, i.e., the damage of cardiomyocytes and the vasculature in the infarcted area.

Clinical Trial Experience

Inspired by experimental data suggesting that functional recovery after MI can be augmented by stem cell transfer,[4,9,10,41,42] several trials were initiated to assess the therapeutic potential of cell therapy in patients post-MI. All clinical studies included patients who had undergone primary angioplasty and stent implantation to reopen the infarct-related artery and who received optimal medical treatment during the acute phase and follow-up. Cells were infused intracoronarily by using the stop-flow balloon catheter approach. Current trials may be categorized into studies that use unselected bone marrow cells or selected stem cell populations.

Unselected Bone Marrow Cells

Following three initial safety and feasibility studies,[31,43,44] four larger randomized trials of bone marrow cell therapy after MI have been completed (Table 3–4).[45-48] The combined experience from these trials indicates that intracoronary delivery of unselected bone marrow cells is feasible and safe in the short- and mid-term (up to 18 months).[49,50] Bone marrow harvest and intracoronary cell delivery are not associated

Table 3–4 Randomized Cell Therapy Trials in Patients with Acute Myocardial Infarction

Study	Design	[*n*]	Cell Type	Dose	Time of Delivery Post-AMI	Outcomes	
						Improved	No Change
BOOST[45]	Randomized-controlled	30 Treated 30 Controls	Nucleated BMCs	128 mL	6 ± 1 days	Global LVEF	LVEDV
REPAIR-AMI[46]	Placebo-controlled	95 Treated 92 Controls	Mononucleated BMCs	50 mL	3-6 days	Global LVEF	LVEDV
Janssens[47] et al.	Placebo-controlled	32 Treated 34 Controls	Mononucleated BMCs	130 mL	1 day	—	Global LVEF LVEDV
ASTAMI[48]	Randomized-controlled	47 Treated 50 Controls	Lymphocytic BMCs	50 mL	6 ± 1 days	—	Global LVEF LVEDV

In BOOST, cells were prepared by gelatin-polysuccinate density gradient sedimentation, which retrieves all nucleated cell types from the bone marrow; REPAIR-AMI and Janssens et al. employed a Ficoll gradient, which recovers the mononuclear cell fraction. In ASTAMI, lymphocytic bone marrow cells were enriched by using the Lymphoprep solution. Dose refers to the average amount of bone marrow that was harvested. AMI, acute myocardial infarction; BMC, bone marrow cell; LVEDV, left ventricular end-diastolic volume; LVEF, left ventricular ejection fraction.

with bleeding complications or ischemic damage to the myocardium. No increased rates of in-stent restenosis have been observed after cell transfer. Clinical surveillance, ambulatory ECG monitoring, and data from an electrophysiological study indicate that bone marrow cell transfer is not associated with an increased propensity to ventricular arrhythmias; moreover, intramyocardial calcifications or tumor formation were not observed after intracoronary bone marrow cell delivery.[45,49,50]

In the BOne marrOw transfer to enhance ST-elevation infarct regeneration (BOOST) trial, intracoronary transfer of nucleated bone marrow cells resulted in an improvement of global left ventricular ejection fraction of 6 percentage points after 6 months compared with the control group. This improvement of ejection fraction was due mostly to improved regional wall motion in the infarct border zone.[45] For comparison, improvements of 3 to 4 percentage points are achieved by primary angioplasty and stent implantation in MI, suggesting that the further improvement of ejection fraction by cell therapy may be clinically meaningful.[51,52]

The beneficial effects of intracoronary bone marrow cell transfer were confirmed in the Reinfusion of Enriched Progenitor cells And Infarct Remodeling in Acute Myocardial Infarction (REPAIR-AMI) trial. In this study, mononucleated bone marrow cell transfer promoted an increase in left ventricular ejection fraction of 2.5 percentage points after 4 months compared with a control group that also underwent bone marrow aspiration but received an intracoronary infusion of a placebo.[46]

In contrast to BOOST and REPAIR-AMI, two other randomized studies did not report significant improvements of left ventricular ejection fraction after intracoronary cell transfer.[47,48] The exact reasons for the differing results remain elusive, and it is worthwhile to take a closer look at the design of these studies (see Table 3–4). In one of the negative studies, cells were delivered very early after coronary reperfusion (i.e., already after 24 hours.)[47] In BOOST and REPAIR-AMI, cells were transplanted several days later. Subgroup analyses in REPAIR-AMI indicate that the timing of cell delivery may be very important, and that the beneficial effects on ejection fraction may be lost when the cells are delivered too early. The Autologous Stem cell Transplantation in Acute Myocardial Infarction (ASTAMI) trial also did not find a significant effect of bone marrow cell transfer on left ventricular ejection fraction recovery.[48] Although the cells were delivered late in ASTAMI (i.e., after 4 to 6 days) a particular cell preparation method that leads to an enrichment of lymphocytic bone marrow cells was employed. It is not clear whether this method actually recovers the bone marrow cell populations that are required to achieve functional improvements after MI. Together, these data remind us that procedural issues, such as the cell preparation method and timing of cell transfer, need to be addressed in future studies.

None of the trials has revealed a significant effect of bone marrow cell transfer on left ventricular end-diastolic volumes, an index of left ventricular remodeling. However, larger studies may be required to settle this issue. Moreover, little data are available regarding the long-term effects of bone marrow cell transfer after MI. Follow-up data from the BOOST trial indicate that the improvements of left ventricular ejection fraction are maintained 18 months after cell transfer; however, ejection fraction also increased somewhat in the control group during long-term follow-up. Analysis of the time course of left ventricular functional improvement indicates that left ventricular ejection fraction recovery occurs significantly faster in the cell transfer group compared with the control group.[50] Tissue Doppler echocardiography analyses in BOOST indicate that bone marrow cell transfer may prevent the development of diastolic dysfunction during long-term follow-up. Significant effects of cell transfer on E/A ratio and tissue Doppler Ea/Aa ratio, but not on isovolumic relaxation time (IVRT), suggest that cell therapy positively affects left ventricular stiffness but not active relaxation.[53]

Selected Bone Marrow Cell Populations

The Transplantation Of Progenitor Cells And Regeneration Enhancement in Acute Myocardial Infarction (TOPCARE-AMI) trial compared mononucleated bone marrow cells with circulating blood-derived progenitor cells (mostly endothelial progenitor cells). Both cell types appeared to have similar safety and efficacy profiles.[49] However, because TOPCARE-AMI was not randomized, firm conclusions regarding the efficacy of endothelial progenitor cells post-MI cannot be drawn at the present time. The effects of culture-expanded mesenchymal stem cells after MI have been investigated in one randomized clinical trial.[54] Although no serious side effects were reported, it is not known whether intracoronary mesenchymal stem cell delivery promoted ischemic damage to the myocardium,[54] a complication that has occurred after intracoronary mesenchymal stem cell infusions in dogs.[55] Six months after cell transfer, regional wall motion and global left ventricular ejection fraction were improved and left ventricular end-diastolic volumes were decreased.[54] These striking effects need to be confirmed by additional studies. In another trial, $CD133^+$ bone marrow cells were infused into the infarct-related artery.[56,57] After 4 months, 6 out of 14 patients had developed in-stent restenosis, and two had developed de novo lesions in the infarct-related artery.[57] These numbers are worrisome; however, the study may be too small to establish a causal relation with $CD133^+$ cell transfer. Although left ventricular ejection fraction increased after $CD133^+$ cell transfer, reliable conclusions regarding efficacy cannot be derived from this small pilot trial.[56]

Stem and Progenitor Cell Mobilization

Data from an initial pilot study suggested that G-CSF may increase the risk of in-stent restenosis in patients with myocardial infarction.[58] This trial, however, has received much criticism, mostly because balloon angioplasty and stenting were delayed until after the course of G-CSF had been completed. G-CSF has the potential to promote neutrophil recruitment to sites of inflammation and tissue injury,[59] which may have contributed to excess neointima proliferation and restenosis in this study. The Front-Integrated Revascularization and Stem Cell Liberation in Evolving Acute Myocardial Infarction by Use of Granulocyte-Colony-Stimulating Factor (FIRSTLINE-AMI) trial randomized 50 patients with MI to a control group or a 6-day open-label course of G-CSF that was initiated within 1 to 2 hours after primary angioplasty and stenting.[60] G-CSF therapy after stent implantation was not associated with an enhanced rate of in-stent restenosis or other serious adverse events and promoted significant improvements in left ventricular ejection fraction and metabolic activity in the infarct territory.[60]

Critics have pointed out that the beneficial effects of G-CSF in FIRSTLINE-AMI were magnified by an unexpected decrease in ejection fraction in the control group.[61] The favorable safety profile of G-CSF post-MI was confirmed in another trial that included 20 patients; this trial did not, however, observe a beneficial effect on left ventricular ejection fraction.[62] Similarly, a randomized-controlled study that involved 114 patients with AMI did not find a significant effect of G-CSF on left ventricular ejection fraction recovery.[63] It remains to be seen whether subtle differences in study design (e.g., the timing of G-CSF application after MI) might account for these discrepant results.

CORONARY ARTERY DISEASE WITH NO MECHANICAL REVASCULARIZATION OPTION

Despite significant advances in coronary revascularization techniques, some patients with coronary artery disease have no revascularization option due to the diffuse nature of their disease. Some of these patients experience anginal symptoms despite maximal medical therapy. Chronic myocardial ischemia can be associated with a regional impairment of contractile function that is partially reversible when tissue perfusion is restored (hibernating myocardium), emphasizing that there is a need for therapeutic strategies aimed at delivering oxygenated blood to the myocardium in these patients. Intramyocardial injection of bone marrow cells or endothelial progenitor cells enhances collateral flow, capillary density, and regional contractility in animal models of chronic myocardial ischemia.[42,64] Because stem and progenitor cells may deliver a natural cocktail of angiogenic and arteriogenic cytokines to the myocardium,[12,64-66] it is conceivable that cell therapy may have advantages above single-cytokine gene therapy approaches to treat myocardial ischemia.[67]

Clinical Trial Experience

Unselected mononuclear bone marrow cells have been used in several small-scale studies in patients with coronary artery disease that is not amenable to conventional revascularization techniques (Table 3–5). Cells were injected into the ischemic myocardium either transepicardially during coronary artery bypass grafting or transendocardially under electromechanical guidance.[39,65,68,69] Together, these early studies suggest that intramyocardial bone marrow cell injections are feasible and, possibly, safe in these patients. Although improvements of anginal symptoms, exercise capacity, regional tissue perfusion, and regional left ventricular systolic function were observed in these studies, firm conclusions regarding efficacy cannot be drawn because of the size and nonrandomized nature of these reports. The experience with transmyocardial laser revascularization has highlighted the need for blinded control groups to control for the placebo effect typically observed in this patient population.[70] Still, the idea to improve myocardial perfusion by bone marrow cell injections is intriguing and should be tested prospectively in larger, randomized clinical trials.

The effects of G-CSF on symptoms and myocardial perfusion has been investigated in 16 patients with intractable angina.[71] Although G-CSF promoted a strong increase in circulating endothelial progenitor cell numbers, there was no evidence of enhanced myocardial perfusion or improved regional wall motion. Furthermore, two patients suffered MIs, raising concerns about the safety of G-CSF in this patient population.[71] Any future trials investigating the role of G-CSF in such patients should employ a careful dose-escalating regimen. However, a serious limitation of any stem cell mobilizing strategy in this patient population may be that circulating cells have insufficient access to the ischemic myocardium.

ISCHEMIC CARDIOMYOPATHY, CHRONIC HEART FAILURE

Chronic heart failure has emerged as a major worldwide epidemic. A fundamental shift in the underlying etiology is becoming evident, in which the most common cause of heart failure is no longer hypertension or valvular disease, but rather long-term survival after MI.[72] Conceptually, replacement of akinetic scar tissue by viable myocardium should improve cardiac function and impede progressive LV remodeling. However, among various potential indications for stem cell therapy, repair of scar tissue may be the most challenging. Transplanted cells will face limited blood supply and may not receive the environmental cues essential for differentiation into vascular cells or cardiomyocytes.

Table 3–5 Non-Randomized Cell Therapy Trials in Patients with Myocardial Ischemia and No Revascularization Option

Study	[*n*]	LVEF	Cell Type	Delivery	Reported Outcomes
Hamano et al[68]	5 Treated No controls	–	Mononucleated BMCs	Transepicardial (during CABG)	Regional perfusion ↑
Tse et al[69]	8 Treated No controls	58 ± 11%	Mononucleated BMCs	Transendocardial (guided by EMM)	Regional perfusion ↑ Regional wall motion ↑
Fuchs et al[65]	10 Treated No controls	47 ± 10%	Nucleated BMCs	Transendocardial (guided by EMM)	Regional perfusion ↑
Perin et al[39]	14 Treated 7 Controls	30 ± 6%	Mononucleated BMCs	Transendocardial (guided by EMM)	Regional perfusion ↑ Regional wall motion ↑

BMC, bone marrow cell; CABG, coronary artery bypass grafting; EMM, electromechanical mapping; LVEF, baseline left ventricular ejection fraction.

Clinical Trial Experience

Skeletal Myoblasts

Following an initial case report,[73] several small trials investigating the safety and feasibility of myoblast transplantation in patients with ischemic cardiomyopathy have been published.[40,74-79] Cells were injected either transepicardially during coronary artery bypass grafting or transendocardially guided by electromechanical mapping (Table 3–6). One major safety concern has arisen from these studies, that is, that myoblast grafts may represent an arrhythmogenic substrate, especially early after cell injection.[80] Concerning the mechanisms of such proarrhythmic effects, it has been proposed that some transplanted myoblasts fuse with cardiomyocytes, thereby generating spatial heterogeneity of Ca^{2+} signaling at the graft-host interface.[81] Moreover, tissue injury and local inflammation could play roles.[74,82] In most trials, improvements of regional wall motion, global left ventricular ejection fraction, and/or tissue viability have been reported after myoblast injections. However, owing to the small number of patients, lack of control groups, and the confounding effect of concomitant revascularization, meaningful conclusions regarding efficacy cannot be drawn at this time.

Table 3–6 Non-Randomized Cell Therapy Trials in Patients with Ischemic Cardiomyopathy

Study	[*n*]	LVEF	Cell Type	Time after MI	Delivery	Reported Outcomes
Menasche et al[74]	10 Treated No controls	24 ± 4%	Myoblasts	3-228 Mo	Transepicardial (during CABG)	Regional wall motion ↑ Global LVEF ↑
Herreros et al[75]	11 Treated No controls	36 ± 8%	Myoblasts	3-168 Mo	Transepicardial (during CABG)	Regional wall motion ↑ Global LVEF ↑ Viability in infarct area ↑
Siminiak et al[76]	10 Treated No controls	25-40%	Myoblasts	4-108 Mo	Transepicardial (during CABG)	Regional wall motion ↑ Global LVEF ↑
Chachques et al[77]	20 Treated No controls	28 ± 3%	Myoblasts	Not reported	Transepicardial (during CABG)	Regional wall motion ↑ Global LVEF ↑ Viability in infarct area ↑
Smits et al[78]	5 Treated No controls	36 ± 11%	Myoblasts	24-132 Mo	Transendocardial (guided by EMM)	Regional wall motion ↑ Global LVEF ↑
Siminiak et al[40]	10 Treated No controls	30-51%	Myoblasts	5-96 Mo	Transendocardial (guided by EMM)	Global LVEF ↑
Dib et al[79]	24 Treated No controls	15-43%	Myoblasts	not reported	Transepicardial (during CABG)	Global LVEF ↑ Viability in infarct area ↑
Stamm et al[83,84]	12 Treated No controls	36 ± 11%	$CD133^+$	3-12 Wk	Transepicardial (during CABG)	Global LVEF ↑ perfusion ↑
Strauer et al[86]	18 Treated 18 Controls	52 ± 9%	Mononucleated BMCs	5-102 Mo	Intracoronary	Regional wall motion ↑ Global LVEF ↑ Viability in infarct area ↑
Assmus et al[85]	73 Treated 23 Controls	40±11%	Mononucleated BMCs Circulating progenitor cells	3-358 Mo	Intracoronary	GLobal LVEF ↑ (only in BMC group)

LVEF denotes left ventricular ejection fraction; $CD133^+$, bone marrow–derived CD133 positive cells; BMC, bone marrow cell; MI, myocardial infarction; CABG, coronary artery bypass grafting; EMM, electromechanical mapping, LVEF, left ventricular ejection fraction.

Bone Marrow Cells

In another pilot study, $CD133^+$ bone marrow cells were injected transepicardially into the infarct border zone in patients undergoing bypass grafting of noninjected myocardial areas (see Table 3–6).[83,84] No procedure-related complications or serious ventricular arrhythmias were observed. After 6 months, perfusion of the cell-injected area and global left ventricular ejection fraction were improved. However, because there was no control group, the efficacy of this approach remains uncertain. In two other trials, patients with ischemic cardiomyopathy were treated with unselected mononucleated bone marrow cells, using the stop-flow balloon catheter technique.[85,86] Similar to patients with MI, the procedure appeared to be safe. Significant improvements of left ventricular ejection fraction were reported in both trials. Notably, one of these studies also included a group of patients receiving an intracoronary infusion of circulating blood-derived progenitor cells; treatment with these cells did not promote improvements of left ventricular systolic function.[85]

THE FORESEEABLE FUTURE OF CARDIOVASCULAR STEM CELL THERAPY

A flurry of small, mostly uncontrolled clinical studies exploring the safety and feasibility of stem cell therapy have been conducted. These studies have used numerous different cell types and preparations, each in a small number of patients with different disease states. Although these clinical studies have generated a great deal of hope, we should take into account the lessons learned from the translation of therapeutic angiogenesis into clinical studies, where great expectations raised by open studies have not been confirmed by subsequent randomized trials. We advocate to no longer perform studies involving small numbers of patients, but rather to conduct intermediate-sized, double-blind, randomized controlled clinical trials to establish the effects of stem cell therapy on surrogate markers, such as left ventricular ejection fraction, myocardial perfusion, or exercise capacity. Upcoming trials should address procedural issues such as the optimal cell type, cell dosage, and timing of cell transfer. These trials may also look at combined morbidity and mortality endpoints, although they may be too small to be conclusive in this regard. Ultimately, outcome trials will have to be conducted.

Notably, the absolute number of transplanted cells did not correlate with subsequent improvements in ejection fraction in previous post-MI studies.[45,87] This may be because the cell numbers infused were within a narrow range, or because of differences in the functional capacity of the cells, such as the ability to home to and engraft in the infarcted area, to undergo transdifferentiation and/or to produce paracrine factors, may override differences in cell numbers. Intriguingly, cell labeling studies indicate that less than 5% of unselected nucleated bone marrow cells are retained in the infarcted area after intracoronary delivery in patients (Fig. 3–5).[34] Although this rate of cell retention was sufficient to improve left ventricular systolic and diastolic function in the BOOST trial,[45,53] it is conceivable that pharmacologic strategies might be used to enhance the homing capacity or other functional parameters

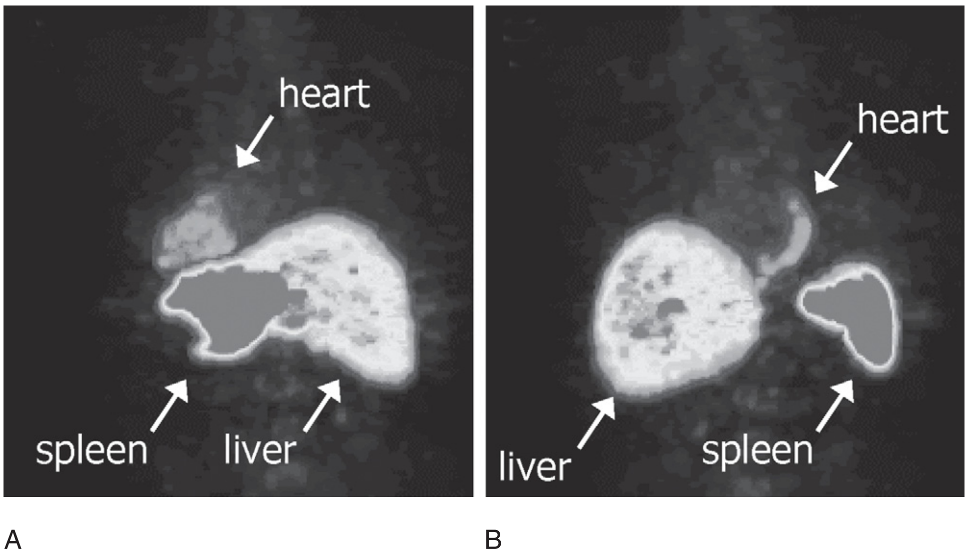

Figure 3–5 (*See also Color Plate 3–5.*) Myocardial homing and biodistribution of ^{18}F-FDG-labeled bone marrow cells after intracoronary transfer. Nine days after primary balloon angioplasty and stent implantation for an acute ST-segment myocardial infarction, this patient received an intracoronary infusion of autologous nucleated bone marrow cells into the stented left circumflex coronary artery. A small fraction of the cells was radiolabeled with 2-[^{18}F]-fluoro-2-deoxy-D-glucose (^{18}F-FDG) just before intracoronary transfer. Positron emission tomography imaging was performed 65 minutes after cell transfer. Left posterior oblique (**A**) and left anterior oblique (**B**) views of the chest and upper abdomen are shown. Approximately 3% of the cells homed to the lateral wall of the heart; most remaining activity is detected in the liver and spleen. (From Hofmann M, Wollert KC, Meyer GP, et al: Monitoring of bone marrow cell homing into the infarcted human myocardium. Circulation 2005;111:2198-2202.)

of the cells. Post-hoc analyses of the BOOST trial database suggest that the effects of bone marrow cell transfer are consistent across several subgroups defined according to sex, age, infarct territory, and time from symptom onset to reperfusion.[45] However, patient subgroups that derive the greatest benefit from cell transfer need to be identified prospectively in future trials (e.g., patients presenting late after symptom onset in whom little myocardial salvage can be expected from reperfusion therapy). In this regard, data from REPAIR-AMI indicate that the effects of bone marrow cell transfer may be more pronounced in patients with more severely depressed baseline left ventricular ejection fraction.[46] G-CSF or other cytokines with stem-cell mobilizing and/or direct cardioprotective properties[88,89] should be further evaluated as stand alone therapy or in combination with cell transfer after MI. Cytokines might evolve as a noninvasive alternative or as an adjunct to cell therapy.

Randomized, double-blind trials with sufficient statistical power are needed to rigorously evaluate the safety and efficacy of myoblasts and other cell types in patients with ischemic heart failure. It may be advisable to restrict the use of myoblast transplantation to patients with an implantable cardioverter-defibrillator. The monitoring function of the ICD will provide critical information on the natural course of myoblast-induced arrhythmias. Post-mortem studies indicate that only a small fraction of injected myoblasts survive in scarred human myocardium.[90,91] Accordingly, preimplantation anti-apoptotic treatments or co-injection of angiogenic growth factors may enhance myoblast survival after transplantation. Another strategy may involve the ectopic expression of connexin 43 in myoblasts, which may permit electrical coupling with resident cardiomyocytes.[92,93] Considering that functional benefits of cell transplantation have been observed in animals with dilated cardiomyopathy,[94] future trials may also want to explore the role of cell therapy in patients with nonischemic heart failure.

Meanwhile, fundamental questions need to be addressed experimentally. What is the fate of the injected cells after transplantation? How long do they survive? Do the cells incorporate, or is transient retention sufficient to promote functional effects? Genetic and transgenic markers should be employed to determine the lineage commitment of engrafted cells. Cell labeling and imaging techniques need to be developed to track stem cell fate in patients and correlate cell retention and engraftment with functional outcomes. Emerging evidence suggests that transplanted cells may interact with resident cardiac stem cells to enhance their regenerative potential. What is the nature and functional relevance of this interaction? Can the regenerative capacity of transplanted stem cells be enhanced by drugs, cytokines, or gene therapy approaches? Pharmacologic and genetic strategies may help to enhance stem cell retention, engraftment, differentiation, and paracrine capability.[16,95-97] The “holy grail” of cell therapy is the replacement of necrotic or scarred myocardial tissue with functional myocytes receiving sufficient blood supply. Although the cell types that have been tested in clinical trials so far (e.g., bone marrow cells, myoblasts) may have a favorable impact on systolic function, they probably do not make new myocardium. This should stimulate further basic research into the prospects of cell types with transdifferentiation capacity, such as ES-cells, resident cardiac stem cells, or multipotent bone marrow-derived stem cells.

Chapter 4

The Process of Regulatory Review for New Cardiovascular Devices*

Neal I. Muni and Bram D. Zuckerman

CHAPTER CONTENTS

Cardiovascular device development has advanced significantly over the last decade, with a remarkable increase in the variety and complexity of available devices and diagnostic tests for cardiac illnesses. Assessment of cardiovascular safety and effectiveness is a challenging, multidimensional task with many groups having important roles in the process. As the key regulatory agency assigned to review and approve of devices in the United States, the Food and Drug Administration's Center for Devices and Radiological Health (CDRH) has an essential, but not exclusive, role in bringing new medical devices to market. It is vital that the FDA effectively interact with the clinical community, industry, and the public at every stage of the medical device life cycle to make the necessary risk and benefit decisions to assist in device development.

This chapter will provide an introduction to the process of regulatory review of new cardiovascular devices, including special challenges faced in the regulation of device treatments as compared with drugs. The chapter will also focus on the evolution of the device regulatory process over the last 10 years, and will include special topics of interest to the practicing physician, including "off-label" use of cardiovascular devices, as well as the responsibilities of cardiologists to ensure the safety and effectiveness of device therapies.

REGULATORY HISTORY OF THE DEVICE REVIEW PROCESS

Although medical devices have been regulated by the U.S. Government since passage of the Federal Food, Drug, and Cosmetic Act ("the Act") in 1938, the FDA's authority was limited to identifying and taking action against sham devices, including pulling them from the market. Over the next 40 years, however, the limitations of this approach became apparent with the growing complexity of device technology and the identification of major safety-related problems with higher-risk medical devices, such as pacemakers and heart valves. As a result of this increased recognition of device complexity and safety concerns, the U.S. Congress, with the assistance of independent medical experts, thoroughly reviewed the existing device laws and initiated a change to the FDA's regulatory mandate for medical devices. Congress understood the importance of fostering continued technological innovation but with improved safeguards to protect the public from an unreasonable level of risk.[1] With passage of the Medical Device Amendments to the Act in 1976, the FDA was formally given the authority to assess device safety and effectiveness as a precondition for marketing approval.

As basically defined by the Act, devices are (1) instruments, apparatus, implants, or in vitro reagents intended for use in the diagnosis, cure, mitigation, treatment, or prevention of a disease or condition; and/or (2) intended to affect the structure or any function of the body that does not achieve its intended use through chemical action and that is not dependent on being metabolized for the achievement of its primary intended purposes.[†] Approaches to clinical evaluation and review of medical devices must take into consideration the diagnostic or therapeutic use for which the device is intended, the technological characteristics of the device, and the level of potential risk inherent to the device.

The Medical Device Classification System

The medical device classification system is a risk-based classification scheme. It forms the basis of the FDA device review process and is unique to devices; drug evaluation does not have a parallel classification system and instead, uses a more uniform process. The Medical Device Amendments of 1976 created three separate classification levels for medical devices based on the device's level of clinical risk. Class I represents a minimal risk device whose safety and effectiveness is well established. Class II devices represent intermediate risk and often require "special controls" such as labeling to ensure safe and effective use. Class III devices are devices of significant risk, with the assessment of risk based not only

*This chapter represents the professional opinions of the authors and is not an official document, agency guidance, or policy of the U.S. Government, the Department of Health and Human Services, or the Food and Drug Administration, nor should any official endorsement be inferred.

†FDC Act" 21 U.S.C. § 201(h).

on the characteristics of the device but also the likelihood of associated morbidity or mortality. Examples of class III cardiovascular devices include most implantable devices, such as intracoronary stents, cardiac pacemakers, and left ventricular assist devices. Other devices, including cardiac diagnostic equipment such as computerized electrocardiographic devices are considered to be intermediate risk (class II).[2] Class I devices are considered of minimal risk and are exempt from pre-market review if they are for the same use as and composed of the same technology as other legally marketed devices. A cardiovascular class I device example is a cardiac chair, designed for proper posture for cardiac and pulmonary treatment.

Any device that was in commercial distribution before the passage of the 1976 Medical Device Amendments is considered a *preamendment* device, and was effectively "grandfathered," being assigned to the least-regulated class that allowed a reasonable assurance of safety and effectiveness. Unless the FDA has taken specific regulatory action to reclassify a preamendment device, it is allowed to remain on the market.

Pathways for Regulatory Review of Cardiovascular Devices

The first step in the device evaluation process is to determine the classification level of the device based on its regulatory requirements. Based on the classification of the device, a medical device manufacturer would usually take either of two key regulatory pathways, the "510(k)" pre-market notification submission, or submission of a pre-market approval (PMA) application, demonstrated in Figure 4–1.

510(k) Pre-market Notification

The 1976 Medical Device Amendments added a pre-market notification provision to Section 510 of the Food, Drug, and Cosmetic Act (section 510[k]), requiring that each firm register its manufacturing facility with the FDA and submit a 510(k) for pre-market review. The first step in the 510(k) evaluation process is to compare the device with existing, marketed class I or II devices (called *predicate* devices) in terms of their intended use, technology, and performance. If the new device can be demonstrated to be *substantially equivalent* to the predicate device, that it is at least as safe and effective, it is cleared for marketing by the FDA. The FDA has a statutory requirement of 90 days to review and make a marketing clearance determination. The manufacturer must receive a letter from the FDA allowing it to market the device before commercial distribution of the device in the United States.

The majority of medical devices cleared for marketing in the United States have done so via the 510(k) pre-market

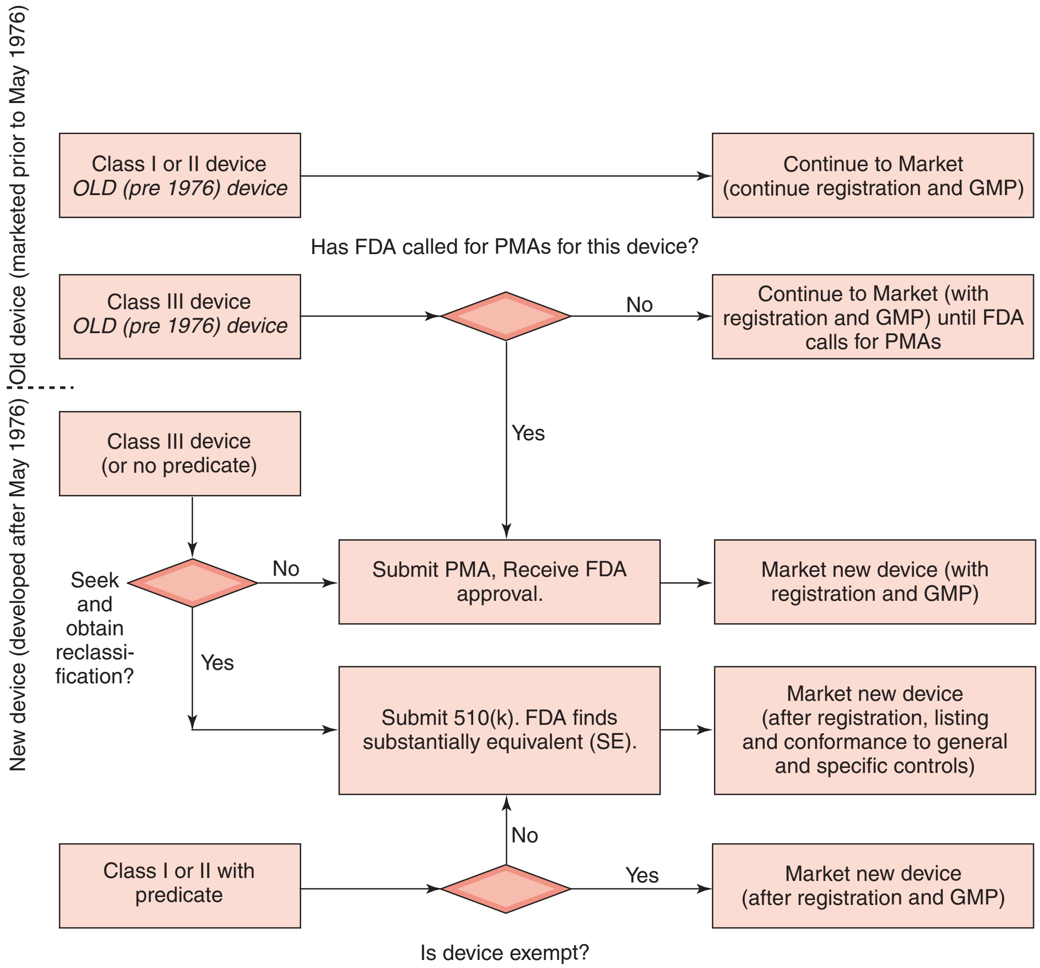

Figure 4–1 Pathways for Regulatory Marketing Clearance and Approval. (Redrawn from the U.S. Food and Drug Administration.)

notification process. As an example, in 2004, a total of 3635 original 510(k) pre-market notifications were received by the Agency, compared with 54 original PMA applications.[3] Approximately 10% to 15% of 510(k) submissions contain clinical performance data. As an example, noninvasive blood pressure (NIBP) cuffs are considered intermediate risk, or class II, devices. Whereas new NIBP devices require appropriate validation by bench and clinical testing, a modification to a previously cleared NIBP device may not need revalidation with clinical testing, depending on the nature of the change, unless the manufacturer plans to market it with a new indication for use or a new fundamental technology. However, other cardiovascular devices classified as class II devices, such as intravascular embolic protection devices, do require clinical performance assessments to make the determination of substantial equivalence.

Pre-market Approval Application

In contrast to class I and II devices that undergo the 510(k) review process, marketing review for higher risk, class III devices must undergo the Pre-Market Approval (PMA) regulatory pathway.* The PMA pathway applies to devices that: (1) are life sustaining or supporting; (2) are of substantial importance in preventing the impairment of human health; and (3) present a potential unreasonable risk of illness or injury.[2 *]

As a condition for FDA approval of a PMA application, a manufacturer must demonstrate a reasonable assurance of the *safety and effectiveness* of a device with respect to its indications for use. For cardiovascular devices classified as class III devices, such as pacemakers, intracoronary stents, and circulatory support devices, to name a few, demonstration of device safety and effectiveness almost always requires clinical performance data to form the basis of product approval. In determining the safety and effectiveness of a class III device, some of the factors considered by FDA include the intended use of the device; the population for which the device is intended; device reliability; and the risk of device use compared with the likely benefit incurred by using the device. To make a determination of product safety and effectiveness, the Agency relies on *valid scientific evidence*.[3 †]

The main goal of FDA device review is to properly assess the clinical utility of the device, based on its risk and benefit profile, to determine product safety and effectiveness. The FDA has a statutory requirement to review a PMA application in a total of 180 days. As will be further discussed in this chapter, the FDA's interpretation of valid scientific evidence for medical device approval has become more rigorous for cardiovascular devices over the last decade, incorporating greater use of randomized, controlled, and even blinded studies when applicable (see Chapter 1).

*21 C.F.R., Part 814.

†21 C.F.R. § 860.7(c)(2) valid scientific evidence is defined as "evidence from well-controlled investigations, partially controlled studies, studies and objective trials without matched controls, well-documented case histories conducted by qualified experts, and reports of significant human experience with a marketed device, from which it can be fairly and reasonably concluded by qualified experts that there is a reasonable assurance of the safety and effectiveness of a device under its conditions of use."

Table 4–1 Comparison of Device and Drug Development

Developmental Feature	Device	Drug
Rate of technology change	Fast	Slow
Ease of in vitro assessment	High	Low
Ability to blind treatments	Difficult	Easy
Influence of physician technique on results	High	Low
Ability to visualize performance after use	High	Low
Pivotal studies required	1	2
Population size	Smaller	Larger

Investigational Device Exemption

Clinical studies performed in the United States using devices that present a significant risk to human subjects (most class II devices and all class III devices) are performed under an approved exemption by the FDA, called an Investigational Device Exemption (IDE). FDA approval of an IDE application gives a manufacturer permission to conduct a clinical study of an investigational device (or an approved device for non-approved indications) on patients in the United States to support the device's safety and effectiveness. As per FDA regulations, the purpose of the IDE is to "encourage…the discovery and development of useful devices intended for human use, while at the same time protecting the public health and ensuring that clinical investigations are performed in a safe and ethical manner."[4 ‡] To maintain optimum freedom for scientific investigators in the pursuit of device development, the statutory time requirement for the FDA to complete its review of an IDE application is 30 calendar days. Clinical data obtained from a study under an approved IDE can then be used to support a 510(k) or PMA application, depending on the pathway necessary for marketing.

Differences in Device and Drug Regulation

There are significant differences in the regulation of devices and drugs by the FDA, largely a result of two main factors (1) differences in the characteristics and use of device and drug therapies; and (2) differences in the regulatory mandate given to the FDA by the U.S. Congress. Table 4–1 provides a comparison of key differences in device and drug development. The differences, as listed in the table, greatly affect the manner in which devices are evaluated compared with drugs, including device-related as well as population-related factors. Of major importance, because a double-blind clinical study is not possible for many cardiovascular device therapies owing to the physical characteristics of the device, the potential for patient and physician-related bias to confound study outcome is increased. For example, in the case of the REMATCH trial, in which end-stage heart failure patients were randomized to left ventricular assist device (LVAD) therapy or optimal

‡21 C.F.R. §812.1(a)

medical management arms,[4] the study could not be blinded for obvious reasons. The inability to blind clinical studies contrasts with the accepted paradigm of double-blinded, placebo-controlled trials for drug therapies.

Many device studies require a "roll-in" phase, owing to time-related improvement in outcome in the use of the device as a result of a physician learning curve. For example, many trials of new robotic surgery assist devices and intravascular embolic protection devices include roll-in phases, such that changes in physician proficiency with use of a new technology can be evaluated vis a vis their impact on clinical performance. There is no comparable learning curve phenomenon for drug administration. Additionally, recipient populations for most cardiovascular devices are proportionately smaller compared with many drug therapies (for example, circulatory assist devices for heart failure patients compared with angiotensin-converting enzyme inhibitor therapy), reducing the sample pool eligible for a clinical study and necessitating smaller device trials compared with drug trials.

Significant differences in FDA regulations affect how devices and drugs are evaluated. For drug therapies, the approval process begins with preliminary testing of a new product in animals, followed by a filing of an Investigational New Drug Application (IND). Clinical testing of an investigational drug usually proceeds in phases, unlike device evaluation. Phase I trials, testing the metabolism and safety of the new drug in a small number of healthy volunteers, is performed initially. Subsequently, phase II studies, generally dose-ranging studies to evaluate safety and efficacy in the patient population, take place, and finally larger phase III pivotal trials evaluating safety and efficacy in a larger, more heterogeneous patient population are completed. Data from these studies are submitted in a New Drug Application (NDA) to the FDA, requesting marketing approval for the investigational drug. The FDA usually requires at least two randomized, controlled, pivotal phase III trials for drug approval, compared with a single trial for device therapies. Post-approval, late stage (phase IV trials, safety registries, effectiveness trials) studies are often conducted to evaluate the effect of the product in various subpopulations and at varying doses or indications, and its long-term benefit and risk profile. The post-approval device evaluation process is discussed in a following section.

Differences in U.S. versus European Device Regulation

The concept of a single European Union (EU) system of medical device regulation is comparatively new and still evolving. In contrast to a single agency in the United States tasked with enforcing regulatory requirements for pre-market notification and pre-market approval of medical devices, the EU currently relies on a system of Notified Bodies for marketing clearance of medical devices. Conformity among the various Notified Bodies, designated and monitored by national authorities within the EU, is guided by three main directives.[5] * The Notified Bodies are responsible for carrying out regulatory inspections of medical device manufacturers and their products under each of the three directives, but the directives are not legally binding to member states. The Directives define the essential requirements that must be met by medical devices when they are placed in commercial use. In general, medical devices can be marketed only if they were subject to a risk assessment, a risk management process, and a risk and benefit analysis. Devices that have met the essential requirements specified by the Directives are then CE Marked by the Notified Body to which an application was submitted for review. The CE Mark is a formal statement of compliance with the requirements of the Directives. Of note, a key difference between U.S. and European regulatory approaches to medical devices is that the U.S. regulatory system is based on confirming that devices are safe and effective for their intended use, whereas the European system is modeled to a large extent on assuring device safety. Although device performance is a concern, the CE Mark indicates only that the manufacturer meets the conformity assessments as established in the Directives.

THE TEMPLE REPORT AND EVOLUTION OF THE DEVICE REGULATORY PROCESS

As discussed in the prior section, the FDA's evaluation of devices is significantly different compared with the evaluation of drugs. However, the device evaluation paradigm has been under a process of evolution over the last decade, incorporating many characteristics typical of drug evaluation. Much of the convergence of the device and drug evaluation processes can be attributed to the recommendations generated by an internal review of the FDA's device approval system in 1993 by the Temple Committee, chaired by Dr. Robert Temple of the FDA's Center for Drug Evaluation and Research (CDER).

The Temple Report and Its Impact on Device Regulation

In the early 1990s, there was growing concern that the FDA was hampered in its ability to properly judge the safety and effectiveness of medical devices owing to limitations in the designs of supportive clinical studies for PMA and 510(k) applications. As a result, the Commissioner of Food and Drugs, Dr. David Kessler, convened a committee primarily composed of clinical and statistical reviewers from CDER, led by Dr. Robert Temple. The Committee on Clinical Review, also known as the Temple Committee, performed reviews on selected pending and approved device applications. The Committee was then asked to make recommendations on improving the clinical review process. The Committee report, also known as the Temple Report, was presented to the public in March 1993.[6] † The Temple Report identified numerous deficiencies in the design and analysis of clinical trials performed by manufacturers for PMA and 510(k) applications.

*Active Implantable Medical Devices Directive (90/385/EEC), June 20, 1990; Medical Devices Directive (93/42/EEC), June 14, 1993; In Vitro Diagnostics Medical Devices Directive (98/79/EC), December 7, 1998. http://europa.eu.int/comm/enterprise/medical_devices/legislation_en.html

†"Final Report of the Committee for Clinical Review: Based on a Review of Selected Medical Device Applications," U. S. Food and Drug Administration, March 1993.

The following key deficiencies were identified by the Temple Committee in its review of selected applications:

- Failure to specify clear hypotheses to be tested and development of clear plans to test them
- Failure to use the most appropriate kind of control or to identify any control group at all
- Use of poorly defined historical controls
- Use of sample sizes inadequate to answer questions
- Poor specification and characterization of patients entering studies
- Poor or no assessment of the comparability of patients in treatment and historical control groups
- Failure to define study endpoints clearly and consistently
- Failure to consider and use blinded evaluation of endpoints where endpoints are subjective

The Temple Committee concluded that, as a result of the identified deficiencies in pre-market submissions submitted to the FDA for review, the FDA was seriously hindered in making appropriate determinations of substantial equivalence or safety and effectiveness for devices. The deficiencies resulted in lengthy review times owing to the multiple requests by the FDA for additional data from the manufacturer. As a result of the Temple Committee's findings and recommendations, CDRH's review and guidance practices have greatly evolved since the 1993 report. Some of the most significant changes include the use of more randomized, controlled studies; better characterization of inclusion/exclusion and success criteria; development of prospective statistical hypotheses and analysis plans; and incorporation of blinding where possible. Although there has been a convergence over the last decade toward drug-like clinical trials, the differences in device versus drug characteristics preclude a completely analogous approach for device and drug regulation. The Division of Cardiovascular Devices at CDRH strives to maximize the use of previously developed drug approaches, while also recognizing that devices are not drugs. Hence, creative approaches, such as the use of nonrandomized studies and propensity score and Bayesian statistical methodology, have become parts of the cardiovascular device clinical trial landscape in certain circumstances (see Chapter 1).[5]

Randomized versus Nonrandomized Studies

Determination of what constitutes *valid scientific evidence* depends on a variety of factors and can vary according to the type of technology and the risk posed by the device. FDA considers data from randomized, controlled clinical trials (RCTs) to be the standard of scientific evidence and encourages use of RCTs in cardiovascular device studies (see Chapter 1). However, use of an RCT study design may be especially challenging in some areas of cardiovascular device development owing to sample size issues or ethical dilemmas. Lack of clinical equipoise for cardiovascular disease management, as in the case of life-sustaining device therapies for end-stage disease, can create ethical dilemmas by mandating that patients be randomized to a study arm that may be perceived by clinicians and/or patients to provide an inferior treatment. The FDA understands that a proper assessment of device technology must balance the competing demands of maximizing scientific validity against the practical realities of performing (and effectively completing) these clinical studies.[6] For this reason, use of nonrandomized clinical studies may be acceptable in certain situations for support of a marketing application. For example, incremental design changes to an existing cardiovascular device, such as an EP ablation catheter, well-characterized with engineering and animal testing data, may be evaluated for safety and effectiveness with a single-arm clinical study in some circumstances. Use of a nonrandomized study design, however, must include the careful selection of a suitable historical control. Additionally, a detailed statistical analysis plan should be developed that accounts for differences in baseline clinical covariates and other time-related improvements in cardiovascular disease management that could bias against historical control data. Statistical methodologies, such as propensity score analysis, could be used as an attempt to increase balance in measured covariates between nonrandomized treatment arms.[7] However, the limitations of propensity score analysis, as well as other means of analysis of nonrandomized data, must be recognized.

Endpoints in Cardiovascular Device Trials

To make a determination of a device's safety and effectiveness, thorough consideration must be given to selection of the most informative and relevant endpoints for clinical trials. For most cardiovascular devices, clinical outcome parameters such as death, myocardial infarction, stroke, length of hospitalization and/or readmission, to name a few, are usually appropriate. Endpoints representing combinations of such clinical parameters, such as major adverse cardiac events (MACE), and target vessel failure (TVF), are often used, either as composite endpoints as described above or as co-primary endpoints with other parameters.

With some cardiovascular devices, successive improvements in device technology have led to decreased rates of adverse events. Improvement in patient outcome is clearly desirable, but has the effect of making comparative analysis between devices more difficult. Coronary drug-eluting stent (DES) technology is one example of this*: the two currently approved DES, the CYPHER Sirolimus Eluting Stent and the TAXUS Paclitaxel Eluting Stent, were tested against bare metal stent controls in their pivotal trials, SIRIUS and TAXUS IV, respectively,[8,9] and demonstrated a reduction in major cardiac adverse event rates.

Given the rapid adoption of DES technology as the standard of care for coronary interventions, current trials for new DES technologies have adopted non-inferiority, active control study designs, in which event rates for both treatment arms are much lower than those observed in bare metal stent trials. Assuming that successive generations of DES have even lower expected adverse event rates, it is expected that study populations much larger than those used in a DES versus placebo study will be necessary to conduct trials with adequate power

*It should be noted that coronary drug-eluting stents are officially classified by the FDA as combination drug–device products, with features of drug as well as device therapies. Based on official designation by the FDA, CDRH has served as the lead review center for DES, with CDER serving a consultative role. Hence, the clinical testing pathway for DES has followed the PMA pathway for device approval.

to discern relevant treatment differences from the noise of clinical endpoints. To allow for a practical and logistically feasible way to prevent an inflation of required sample size to preserve study power, alternative strategies to determine product effectiveness may be appropriate.

Surrogate endpoints have been suggested as alternate outcome measures for technologies such as DES. Angiographic markers of restenosis, including diameter stenosis and late lumen loss, are potential surrogate markers for clinical effectiveness endpoints. These angiographic outcome measures have the advantage of providing quantitative data for comparison, even in patients who have not developed a major clinical adverse event, and consequently have the potential for increasing the effect size of outcome measures between treatments. Other biomarkers have been proposed as surrogates for other device studies, such as myocardial infarct size and electrocardiographic ST-segment resolution for intracoronary embolic protection devices. An increase in outcome rates and/or magnitude of measured events has the benefit of reducing the required sample size for adequate power to evaluate product effectiveness. Although the use of biomarkers as surrogate endpoints has potential advantages, proper validation of the surrogate variable must be undertaken to fully characterize its predictive capabilities compared with clinical outcomes. The appropriate manner in which to characterize and validate biomarkers for use as surrogate variables in device trials remains a point of contention.[10,11]

Study Blinding in Cardiovascular Device Trials

Although the use of study blinding reinforces the integrity of the random allocation and treatment effect of patient assignment in RCT study designs, for most cardiovascular devices, designing a purely blinded RCT can be impractical and logistically impossible because of the physical characteristics and/or the mode of action of the device. However, it is very important to consider the potential for considerable investigator and/or patient bias introduced by knowledge of treatment assignment, possibly confounding clinical study outcomes and diminishing the scientific validity of a study. Study designs should, therefore, incorporate blinding to the maximum extent possible, maintaining the blind for patients, follow-up study investigators, and study staff to minimize the potential for bias and confounding, whenever logistically implementable. In addition, increasing the objectivity of study outcome parameters as much as possible, and including special analytical methods to evaluate for the potential influence of bias in study outcome are potential ways to maximize the scientific validity of study design.

As an example, the pivotal studies conducted for the CYPHER and TAXUS drug-eluting stents used double-blind study designs, given that the products visually and radiographically were similar in appearance. However, with noninferiority DES trials, in which stents with different platforms are being used, the cardiac catheterization laboratory staff is aware of treatment assignment because of the unique physical properties of each product. Hence, a single-blind approach has been recommended in which patients, the device manufacturer, and study staff, except for the cardiac catheterization laboratory staff, are all blinded to treatment assignment.

Use of Foreign Data for U.S. Product Approval

Increasingly, studies for cardiovascular devices are conducted in centers outside the United States (OUS). The FDA is allowed to consider OUS data as supportive evidence for U.S. product approval.* However, as specified in the regulation, OUS data must be demonstrated to be *applicable to the U.S. population and practice of medicine*. Unless consideration of the potential differences in patient populations and study characteristics is made before initiating OUS studies, such data might have limited applicability.

There are potential advantages to combining data from different studies, including the ability to evaluate device performance across a broader population than can be achieved by one study alone. In addition, multiple studies performed at different sites could potentially increase the generalizability of study results because of wider demographic and geographic inclusion. Furthermore, demonstration of comparable device performance across different studies can provide a more robust conclusion of product safety and efficacy.

A key consideration when assessing the applicability of OUS studies in support of product safety and effectiveness is to evaluate the generalizability of the OUS studies to the patient population in the United States. Important factors include patient-related demographic and clinical characteristics, geographic differences in medical practice, and differences in study protocol. These factors have the potential to affect cardiovascular device performance in terms of both safety and effectiveness. Planned statistical analyses could be used to evaluate the comparability of U. S. and OUS data, by testing the homogeneity of demographic and procedural covariates across centers and geographical regions as well as testing for interactions between treatment and region.

Independent Oversight of Cardiovascular Device Trials

Many cardiovascular device studies evaluate breakthrough approaches that have novel technologies and potential unforeseen risks to patients enrolled in clinical trials. To ensure adequate protection of patient safety, the FDA has increasingly recommended the use of independent Data Safety and Monitoring Boards (DSMB) (see Chapter 1). Study DSMBs should have adequate monitoring plans to adequately ensure that patients are not subjected to undue risk. In cases where cardiovascular devices are evaluated in multiple, concurrent trials, it may be appropriate to use the same DSMB to streamline safety monitoring from a "global" perspective.[12]

In the spirit of the Temple Commission report, the FDA has increasingly recommended the use of independent oversight and adjudication committees to avoid potential issues of conflict-of-interest and external bias. Interpretation of cardiovascular trial data by independent core labs, with adjudication of clinical events completed by a clinical events committee (CEC), complements the role of the study DSMB by further reinforcing study integrity and independent monitoring.

---

*21 CFR § 814.15.

RISK, BENEFIT, AND THE PRODUCT LIFE CYCLE

The regulatory mandate given by Congress to the FDA was to ensure a *reasonable assurance* of a device's safety and effectiveness before allowing the device to be marketed. The requirement of reasonable assurance reflected the understanding that there was no regulatory mechanism that would guarantee *absolute* safety and effectiveness of a medical device. Implicit in the requirement for reasonable assurance was the recognition that the context of the risk and benefit profile of the illness being treated is essential to determine a device's safety and effectiveness. In other words, effective medical devices may have the capacity to do harm, and an assessment of a device's safety and effectiveness should take into account the device's risk weighed against the potential benefit in terms of clinical utility. Although the reasonable assurance mandate allows the FDA to rely on prudent risk and benefit assessments in its decision-making process, this requirement adds to the complexity of the FDA's task in determining the appropriate level of information needed before allowing a product to be marketed, given that there is no "one size fits all" approach for medical devices. Throughout a device's life cycle, risk and benefit assessments must be made by the FDA to protect and promote public health.

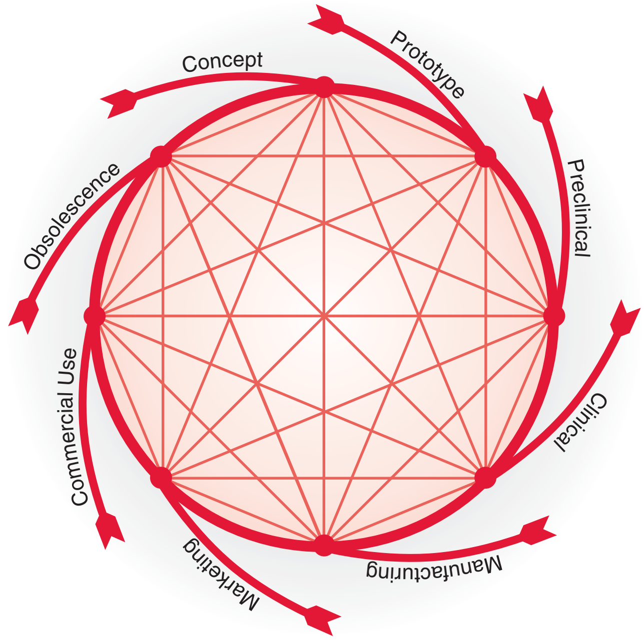

Figure 4–2 The Total Product Life Cycle. (Redrawn from the U.S. Food and Drug Administration.)

The Total Product Life Cycle Approach

All medical devices have a finite product life cycle, from the concept phase to product obsolescence (Fig. 4–2). The FDA views device development in terms of a continuum of development phases, in which product risk and benefit evaluation must take place across all stages of the product life cycle. Compared with drug therapies, the product life cycle for most cardiovascular devices is much shorter, with an average concept-to-obsolescence time between 1 and 2 years, compared with many years for an average drug. The optimal regulatory strategy must take into account the rapid product life cycle of cardiovascular devices. Novel approaches are necessary to evaluate serial iterations of existing technologies, so that a product is not confined to obsolescence after completion of a clinical trial designed to test the first generation device. Allowing manufacturers to submit supplements to already approved PMA applications is one approach to streamline the regulatory review process for incremental device changes. In addition, approaches to device regulation must view the product life cycle in its entirety, viewing the pre-clinical development, clinical testing, and marketing of a device not as divided phases but as a continuing spectrum of development.

Striking an Appropriate Pre-approval/ Post-approval Balance

One of the most complex tasks faced by the FDA for class III devices is finding the proper balance between assessing product safety and effectiveness versus making promising therapies readily available to the public. To achieve an appropriate balance, the FDA must consider several competing factors across all stages of a product development life cycle. For example, initiation of a clinical study requires the adequate determination of safety based on pre-clinical laboratory, engineering, and animal testing. Approval of class III (and some class II) devices for marketing subsequently requires an adequate determination of safety and effectiveness based on data generated from clinical testing. Risk and benefit evaluation continues in the post-approval setting, by means of device safety evaluation when used in "real world" clinical practice, including important cohorts of patients often not tested in initial testing for product approval. The optimal pre-approval/post-approval balance for collecting device safety and effectiveness information must weigh the risks of allowing an incompletely tested product to be marketed to the public against the risks of delaying a potentially lifesaving or life-enhancing product from being made available to patients.

The Cardiologist's Role in Assuring Device Safety and Performance

The primary goal of the FDA in evaluating cardiovascular devices is to ensure that the devices are safe and effective—in other words, that the products confer maximum benefit on patients without imposing unreasonable risks. FDA uses a variety of regulatory tools, applied before the marketing of a product as well as after it is in widespread use, to assist in assessing product safety and effectiveness. However, making sure that devices are safe and effective is a task for which the FDA's efforts can go only so far. Clinicians have a vital role to play in completing this process: by knowing the clinical indications of the devices they use, by understanding and documenting the potential adverse effects they may encounter, and by informing patients about benefits and risks.

Specifically, it is important for all physicians to review a product's instructions for use (IFU) statement, usually an insert included within the device packaging, regarding the populations tested in supportive clinical studies, and to be

thoroughly familiar with the approved indications for use as well as the instructions for using the product. It is equally important that clinicians and support staff at health care facilities be familiar with the FDA's MDR system for product-related adverse events, and that they report such events expeditiously.* Without the reports of device-related adverse events submitted by physicians and health care facilities, the FDA would be impeded in identifying a potential safety problem with a device.

ENSURING THE SAFETY OF MARKETED DEVICES

Although pre-clinical and clinical testing of cardiovascular devices provides invaluable information on short-term safety and effectiveness in a select population, performance of a device in populations not specifically tested in clinical trials ("real world" use) and over the long-term are not addressed by such testing. Furthermore, pre-clinical and clinical studies performed for device approval might not detect certain low-occurrence events but would detect catastrophic adverse events that would render an investigational product unacceptable for general use. Such low-occurrence events might be detected only in large-sample study populations and over longer follow-up periods, making it necessary to gather further information in actual clinical use. Hence, there is a need for continued device evaluation after a product is allowed on the market.[13]

Post-market Safety Assessment Tools

The increased speed of technology turnover, shorter product life cycles, and the prohibitive cost of conducting full-scale, randomized clinical trials for medical devices contributes to the importance of post-marketing surveillance studies to evaluate long-term device performance. Surveillance of medical devices post-approval provides a system in which risks and benefits can be assessed in a larger population and over a longer period of follow-up than would be achievable in the pre-marketing phase. Unanticipated risks secondary to product manufacturing changes, device modifications, or human factors (such as changes in operator technique) usually cannot be adequately tested in pre-clinical and clinical testing models.

Effective post-approval identification of device risks relies on the active collaboration of device manufacturers, regulatory bodies, physicians, and health care facilities to detect and report device-related injuries and other adverse events. Given the differences in regulatory mechanisms in the post-market oversight of medical devices compared with pre-market regulations, post-market device evaluation is largely dependent on information provided voluntarily by device manufacturers and health care providers.[14]

There are several different methods to collect post-approval clinical information for devices, each with differing levels of scientific validity. Table 4–2 provides examples of different post-approval device study methodologies, from the highest level of scientific rigor to purely qualitative, adjunct forms of data collection. Under current Medical Device Reporting (MDR) regulations, the FDA requires that device manufacturers report all device-related deaths and serious injuries to the Agency. One difficulty the FDA faces in assessing adverse event information obtained by this route is that underreporting of adverse event information, especially by clinicians and end-users, is widespread. Furthermore, given the absence of denominator information (the total number of devices actually used), assessment of adverse event rates is not reliable via this mechanism. Accurate determination of adverse event rates requires a controlled study with defined follow-up periods.

Table 4–2 Examples of Post-approval Data Collection Methods

- Randomized, blinded controlled clinical trial
- Randomized, nonblinded clinical trial
- Comparative and noncomparative cohort clinical study
- Case-control study
- Registry study
- Survey
- Active surveillance
- Passive Surveillance via Medical Device Reporting (MDR) system, Medical Device Safety Network (MedSun), and International Vigilance

Examples ranked in order of level of "scientific rigor," starting from the most scientifically valid method of data collection to purely descriptive and potentially more biased forms of obtaining data.

Pre-market and Post-approval Integration

To enhance integration of the pre- and post-approval stages of device risk and benefit evaluation, a novel mechanism using continued access, "peri-approval" registry studies has been used for two drug-eluting stents under development.[10 †] To expedite the acquisition of traditional post-marketing data, the FDA has allowed the initiation of post-approval registry studies during the pre-approval stage in these circumstances, permitting a manufacturer to continue collecting data under the auspices of the original clinical study, but with expanded clinical access, for post-approval device evaluation. Such an approach has the benefit of allowing for quicker initiation of post-approval studies as well as providing additional acute safety data to support marketing approval itself for the device. Approval of the pre- and post-marketing study plans simultaneously allows for continuous enrollment without gaps

*Adverse events can be reported online at http:www.fda.gov/cdrh/mdr.

†"CYPHER sirolimus-eluting coronary stent on RAPTOR over-the-wire delivery system or RAPTORRAIL rapid exchange delivery system—P020026." Rockville, Md.: Food and Drug Administration, April 24, 2003. (Accessed July 25, 2005, at http://www.fda.gov/cdrh/pdf2/p020026.html.) and "TAXUS Express 2 paclitaxel-eluting coronary stent system(monorail and over-the-wire)—P030025." during FDA review and approval decision-making, and accommodates IRB approval during the initial clinical phase of the study, thereby minimizing potential delays in commencing the peri-approval registries. The benefit of the peri-approval approach is that both the FDA and a device manufacturer can, in a timely fashion, assess patient safety in a more representative, "real-world," use of the device.

Off-Label Use of Cardiovascular Devices

One of the most important aspects of the device approval process is the development of a meaningful and accurate product label, which includes the indications for which the product is approved, instructions for use, and patient-related information. The FDA works closely with the device manufacturer to create the product label. The label also includes details regarding the clinical studies performed in support of the product's approval, and the specific population tested in clinical studies.

Physicians may want to use a device in a manner different from the labeled indication (i.e., an "off-label" use) because the beneficial effects seen in clinical trials may transfer to relatively untested patient subgroups. A legally marketed device may be used as the physician deems appropriate to benefit an individual patient as part of the *practice of medicine*. However, both the physician using an off-label device and the patient on whom the device is used should understand that the off-label use may not have been tested sufficiently to establish its risk and benefit profile, and that generalization of available trial results to broader patient populations may not be appropriate.

Although off-label use by a physician in the routine practice of medicine is not within the FDA's regulatory purview, the Agency is concerned that off-label device use diminishes the incentive for a manufacturer to study or seek FDA approval for the indication for which the product is being used off label. Additionally, not having adequate data to evaluate the safety and effectiveness of devices in important patient subsets limits the ability of a clinician to decide whether or not a specific product is appropriate for their patient, and greatly hinders the process of appropriately informing patients of the risks and benefits of such therapy.

If physicians use a device for an indication not in the approved labeling, they have the responsibility to be well informed about the product, base the product's use on firm scientific rationale and on sound medical evidence, and maintain records of the product's use and effectiveness. Specific language introduced by the FDA Modernization Act of 1997 addressed "practice of medicine,"* stating that *nothing in this act shall be construed to limit or interfere with the authority of a health care practitioner to prescribe or administer any legally marketed device to a patient for any condition or disease within a legitimate health care practitioner–patient relationship.* However, the Act did make clear that promotion of medical devices did fall under the Agency's purview, and therefore, promotional activity for medical devices must be consistent with the device's approved labeling.

*21 U.S.C. 396 § 906, see also Food and Drug Modernization Act of 1997 § 214.

CONCLUSION

As part of the responsibility to protect the public health, the FDA faces many challenges in the evaluation of new cardiovascular devices. Given the rapid advancement of cardiovascular device technology, the FDA must determine how to best achieve its mandate with the resources at its disposal. It is clear that an active collaboration of industry, the clinical community, and regulatory agencies is essential to maximize efficiency and best expedite the advancement of new technologies across all stages of the product development life cycle. Along with the anticipated changes in the technological and clinical landscapes of cardiovascular medicine, the FDA's technology assessment programs will continue to evolve to maximize regulatory efficiency and to provide the most appropriate means of evaluating risk and benefit of medical devices. At the same time they must ensure that beneficial therapies are made available to patients in a timely manner.

Ischemic Heart Disease

Chapter 5

Pharmacologic Options for Treatment of Ischemic Disease

Jonathan Abrams, John Schroeder, William H. Frishman, and Jane Freedman

CHAPTER CONTENTS

THE ORGANIC NITRATES

Organic nitrates, therapeutic agents that have been used to treat angina for more than 125 years, are known as putative exogenous nitric oxide (NO) donors.[1] They are rapidly converted to NO, which activates guanylate cyclase in smooth muscle cells and platelets. This results in the production of cyclic guanosine monophosphate (cGMP), with subsequent vascular relaxation and platelet antiaggregatory effects (Fig. 5–1). Normally, in response to a number of physiological stimuli, particularly shear stress, intact vascular endothelium releases endogenous NO, which causes vasodilation. It has been speculated that NO donors (e.g., nitrates) may circumvent the requirement for normal endothelial function and promote vasorelaxation even when the endothelium is damaged or dysfunctional (i.e., the organic nitrates may represent an exogenous source of NO). This hypothesis has not been proved, and there are no clinical data supporting the concept that organic nitrates can effectively replace endogenous NO, with a concomitant improvement in vascular function of subjects with endothelial dysfunction. Furthermore, considerable data suggest that nitrates can actually induce endothelial cell dysfunction.[2]

Mechanisms of Action

Pharmacodynamics

The major action of the nitrates is to produce *vasodilatation*, which occurs most prominently in the venous capacitance vessels, the large coronary arteries, and, to a much lesser extent, in the peripheral arterioles and microvasculature.[3,4] Through a reduction of preload and afterload, oxygen uptake of the heart is decreased by about 20% to 40%.[3] The fall in myocardial oxygen demand reflects reductions in venous return and both left and right ventricular volumes, along with a modest fall in arterial pressure, although these benefits may be to some extent offset by a reflex increase in the heart rate.[5]

Nitrates have direct effects on the coronary circulation because they dilate large coronary epicardial arteries and arterioles that are more than 100 μm in diameter. Nitrates do not effectively dilate the smaller arterioles or resistance vessels, possibly because the enzymes responsible for converting organic nitrate to NO are relatively inactive or absent in the smaller coronary arterioles and microcirculation.[5] By dilating large coronary arteries, nitrates may favorably redistribute blood flow to collateral channels and blood flow from epicardial to endocardial regions, as well as attenuate exercise-induced coronary arterial constriction and spontaneous coronary spasm.[4] In addition, these agents may prevent or reverse constriction of sites of coronary stenoses. An important clinical distinction is that agents such as dipyridamole and other vasodilators, including sodium nitroprusside (SNP) that act directly on small arterioles and the microcirculation may induce a *coronary steal* effect by diverting nutrient blood flow from ischemic regions of the myocardium.[6]

Vascular Signaling Systems

The production and release of endogenous NO (see Fig. 5–1) are recognized as having an extraordinarily important physiological role that extends beyond the cardiovascular system.[7] Nitrate biotransformation to NO may occur near the plasma membrane of vascular smooth muscle cells; a certain amount of extracellular transformation of organic nitrate to NO also takes place.[8,9] The activity of the enzyme glutathione-*S*-transferase as well as the presence of thiol groups may

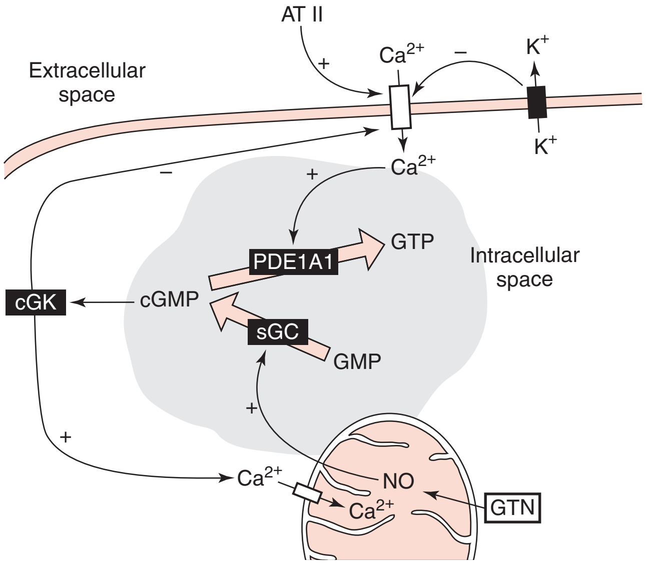

Figure 5–1 **Mechanisms of nitrate action**. GTN is metabolized to NO, which stimulates the synthesis of cGMP. In turn, cGMP reduces cytoplasmic Ca^{2+} by inhibiting inflow and stimulating mitochondrial uptake, causing relaxation of smooth muscle cells. The role of Ca^{2+}-activated K^+ currents is also being investigated. By inducing hyperpolarization of the cellular membrane, they might contribute to the limitation of Ca^{2+} entry in smooth muscle cells and, in endothelial cells, they might inhibit O_2^- production. By promoting Ca^{2+} uptake, ATII can increase cytoplasmic Ca^{2+} and induce the Ca^{2+}-dependent PDE1A1. This may lead to reduced cGMP and cGK activity, providing an elegant explanation for both nitrate tolerance and increased sensitivity to ATII. There is evidence supporting a redox sensitivity of all enzymes involved in these processes. PDE1A1 indicates phosphodiesterase 1A1; GTP, guanosine triphosphate; cGMP, cyclic guanosine monophosphate; AT II, angiotensin II. (Redrawn from Gori T, Parker JD: Nitrate tolerance: A unifying hypothesis. Circulation 2002; 106:2510.) (Note: GTN = NTG = nitroglycerin. The abbreviations GTN and NTG are used interchangeably in the text and figures in this chapter.)

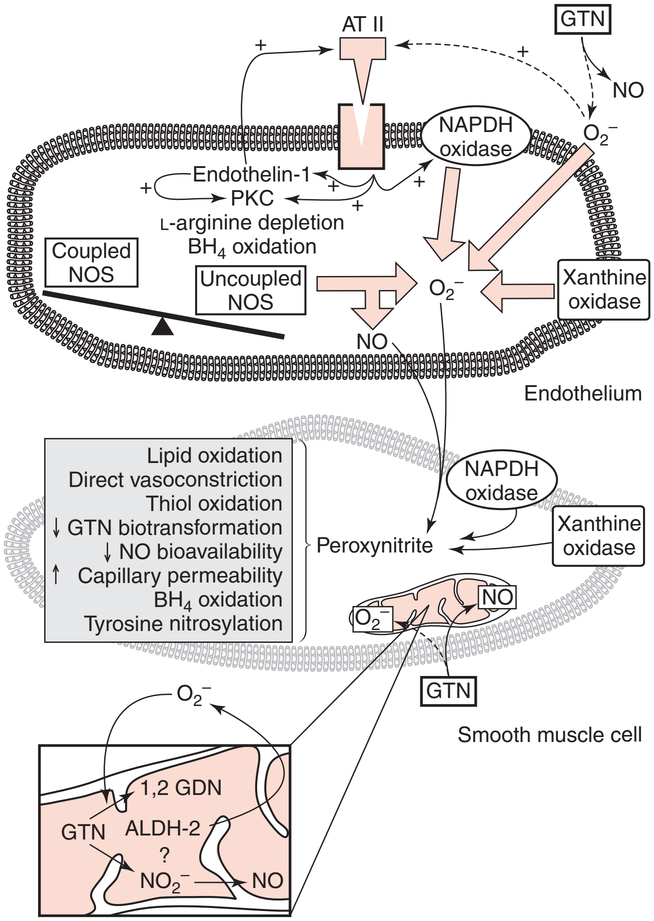

Figure 5–2 **Proposed mechanisms of nitrate tolerance, emphasizing oxidative stress**. Diagram depicting the proposed pathways for the development of nitrate tolerance. Both endothelial and smooth muscle cells are involved in these processes. Superoxide anion is produced by membrane oxidases and, possibly, during nitroglycerin (glyceryl trinitrate; GTN) biotransformation (*dashed arrow*). Increased angiotensin II (AT II) production and responsiveness and increased oxidative stress may result in uncoupling of nitric oxide synthase (NOS) and further production of reactive oxygen species and peroxynitrite. In turn, these oxidant-free radicals may cause many of the abnormalities observed in nitrate tolerance. Isoprostane formation and increased capillary permeability might be responsible for plasma volume expansion, and tyrosine nitrosylation and thiol group oxidation might be responsible for inactivation of multiple enzymes—including those involved in the biotransformation of nitroglycerin. Tetrahydrobiopterin (BH_4) oxidation may cause NOS uncoupling. PKC, protein kinase C; O_2^-, superoxide anion; GDN, glyceryl dinitrate; NO_2^-, nitrite. (Redrawn from Parker JD: Nitrate tolerance, oxidative stress, and mitochondrial function: Another worrisome chapter on the effects of organic nitrates. J Clin Invest 2004;113:352.)

be required, but this remains controversial. Not all data are consistent with this hypothesis, and other enzyme systems—including an esterase and a microsomal cytochrome P450—have been reported to produce NO even in the absence of sulfhydryl groups.[10] Sulfhydryl-dependent metabolism has been thought to be important to the development of nitrate tolerance,[11] although recent work has de-emphasized this older concept. Especially promising is the suggestion that biotransformation of nitroglycerin (NTG) occurs predominantly in mitochondria through a novel reduction of mtALDH (mitochondrial aldehyde dehydrogenase or ALDH-2) (Fig. 5–2).[1,9,12-15] Furthermore, Chen and colleagues believe that "attenuated biotransformation of NTG by mitochondrial ALDH underlies the induction of nitrate tolerance"[9,12] (see later). The importance of mitochondrial ALDH in modulating the development of nitrate tolerance, however, is controversial and not accepted by some authorities in the field (J. Horowitz, personal communication, 2005). Arguments against a central role for mitochondrial ALDH in producing tolerance include

1. ALDH can be inhibited by NTG under conditions in which almost no tolerance is induced.
2. ALDH inhibitors produce the same effects in tolerant and nontolerant vessels.
3. Chinese subjects who lack ALDH2 respond either normally or nearly normally to NTG at both vascular and platelet levels.

Nitrates are more active in venous tissue than in arteries, and vascular uptake of nitrate is more avid in the veins than in the arteries.[16] The rate of formation of cGMP is surprisingly greater in arteries than in veins.[17]

Effects on Platelets

A modest inhibitory effect of nitrates on platelet aggregation has been demonstrated in vitro, ex vivo, in normal subjects, and in patients with angina or recent acute myocardial infarction (MI). Low concentrations of nitroglycerin (NTG) can partially reverse adenosine diphosphate (ADP)-induced platelet aggregation.[18] The clinical significance of this effect is unknown, but antiplatelet activity after nitrate administration may play a beneficial role, particularly in unstable angina.[4,19]

Intracellular Actions of Nitric Oxide

NO stimulation of guanylate cyclase results in cGMP production, in turn activating a cGMP-dependent protein kinase.[10] This kinase decreases cytosolic calcium levels in vascular smooth muscle cells—the "ultimate step" in vascular contraction. The mechanism for the fall in calcium levels is not yet well understood but might involve (1) increased uptake of Ca^{2+} into the sarcoplasmic reticulum (after phosphorylation of phospholamban); (2) decreased release of Ca^{2+} from the sarcoplasmic reticulum after a fall in inositol-1,4,5-triphosphate; or (3) inhibited contraction after decreased phosphorylation of the controlling enzyme in vascular smooth muscle contraction—namely, myosin light-chain kinase. cGMP also has direct effects on monovalent cation transport. Furthermore, NO has effects on potassium channels independent of cGMP. Thus, the pathways involved in nitrate-induced vasodilatation remain uncertain, although those shown in Figures 5–1 and 5–2 represent one current view of nitrate biotransformation. Not all investigators are in agreement with this scheme.[11]

Direct Effects on Myocardium

The direct action of NO on cardiac muscle produces a negative inotropic effect,[20] which could contribute to the anti-ischemic protection of nitrates. The potential messenger for myocardial responsiveness to NO may also be cGMP, which by lowering cell calcium levels could theoretically protect against calcium-mediated ischemic damage and arrhythmias.

Summary of Hemodynamic Actions of Nitrates

The predominant clinically relevant effect of the nitrates is a combination of preload reduction, modest reduction in afterload, and dilatation of large epicardial coronary arteries (including nonobstructed sites of vasoconstriction or at the coronary stenosis) (Table 5–1).[3,4] Other mechanisms of action, such as those on platelets, prostaglandins, and cardiac myocytes, are not yet definitely established as being important in reducing myocardial ischemia.

Pharmacokinetic Properties of Nitrates

The pharmacokinetic properties of the individual organic nitrates vary greatly (Table 5–2).

Nitroglycerin. Plasma NTG levels, difficult to measure, transiently increase in the case of sublingual NTG, and result in sustained blood levels with transdermal NTG patches. With continuous NTG delivery systems, NTG levels are maintained relatively constant for a 24-hour period, although there is intra-individual and inter-individual variability. Transdermal NTG patches should be removed after 12 to 14 hours of use each day.

Isosorbide dinitrate and isosorbide mononitrate. Hepatic first-pass extraction converts circulating isosorbide dinitrate (ISDN) to isosorbide-5-mononitrate (5-ISMN), the active component, and, to a lesser extent, to 2-mononitrate. All three of these compounds reach high concentrations in the plasma. Approximately 50% to 60% of the parent compound ISDN is converted to 5-ISMN.

5-ISMN is completely absorbed with nearly 100% bioavailability. Both standard and controlled-release formulations have been extensively studied. Whenever steady-state blood levels of the organic nitrates are maintained for a significant period of time, nitrate tolerance may develop. Long-term dosing schedules designed to avoid nitrate tolerance are established for 5-ISMN (two 20-mg doses of the standard preparation are administered 7 to 8 hours apart), as well as for ISDN (maximum of two or three doses per day). Controlled-release ISDN or 5-ISMN preparations are administered as a single dose once daily. Standard doses and preparations are shown in Table 5–2.

Indications for Nitrates

Nitrates are used for the treatment of a wide variety of anginal syndromes, including acute effort angina (sublingual, buccal, or oral spray NTG); stable angina prophylaxis (oral, topical, or buccal); unstable angina (intravenous, topical, or oral); acute MI (intravenous); and congestive heart failure (intravenous, topical, or oral).

Nitrate Therapy for Congestive Heart Failure

The combination of long-acting nitrates and hydralazine was one of the first regimens to show that vasodilator therapy could favorably influence outcome in chronic heart failure.[21] Several studies have documented favorable acute hemodynamic benefits with organic nitrates, which include lowering of left ventricular filling pressure (pulmonary wedge pressure of LVEDP) and lowered pulmonary artery pressure, accompanied by only small changes in blood pressure.[22-24] Higher nitrate doses than those used in angina pectoris are usually necessary in heart failure, such as 60 to 90 mg of oral ISDN, 2 to 3 inches of NTG ointment, or 0.6 to 1.0 mg/hr transdermal NTG. Intravenous NTG or ISDN may be especially useful in critically ill patients in florid congestive heart failure. A study from Israel demonstrated superior efficacy of high-dose intravenous ISDN compared with high-dose furosemide plus low-dose ISDN in subjects with severe pulmonary edema.[25] The African-American Heart Failure Trial (A-HeFT)[26] may stimulate increased use of an ISDN-hydralazine combination in heart failure (see later). It is likely that nitrate therapy in heart failure is underused by many physicians. A survey of >300 heart failure specialists confirms use of nitrates in up to 80% to 90% of such patients, with greater use in sicker subjects.[27] Coadministration of hydralazine was reported in at least 25% of patients.

Table 5–1 Beneficial Effects of Nitrates in Angina Pectoris: Potential Mechanisms of Action

Peripheral or Systemic Actions	Result
Venous dilation (systemic and pulmonary veins)	Smaller right and left heart volumes (preload and afterload) Lower right and left heart filling pressures (preload) Altered LV pressure-volume relationship
Arterial dilation	Reduced arterial reflectance wave Decreased systolic blood pressure Increased arterial compliance Decreased aortic impedance Increased efficiency of LV ejection Decreased LV afterload
Arteriolar dilation (high doses)	Decreased systemic vascular resistance Decreased afterload
Central or coronary action Coronary artery (epicardial) vasodilation Prevention/reversal of coronary artery vasoconstriction and spasm Coronary stenosis dilation (eccentric lesions) Enhanced collateral caliber and flow Prevention of distal coronary vessel and/or collateral constriction Preserved coronary vasodilator response in the presence of endothelial dysfunction Dilation of small (resistance) vessels with large doses	All actions: increased global and/or regional coronary blood flow, especially during ischemia
Endothelial function Nitrates converted to nitric oxide within vascular smooth muscle cell, which diffuses into lumen	Vasodilation and antiplatelet action in the absence of normal endothelial function
Antiplatelet actions* Decreased platelet aggregation and adhesion	Potential antithrombotic benefit in unstable angina and acute myocardial infarction

*Controversial.
LV, left ventricular.

Nitrate Tolerance

The phenomenon of nitrate tolerance, once under dispute and ignored by many clinicians, is now established beyond reasonable doubt. The precise mechanism or mechanisms involved remain incompletely resolved (see Fig. 5–2). Nitrate tolerance occurs clinically whenever nitrate blood levels are sustained for many hours without a nitrate-free interval or major fluctuations in nitrate levels. Of interest, organic nitrate plasma levels are elevated in the presence of tolerance. Tolerance has been documented during nitrate treatment of congestive heart failure as well as in stable angina pectoris. Although there is relatively little direct evidence for tolerance when intravenous nitrates are administered for unstable angina or acute MI, increasing dosage is often required to control chest pain; it is likely that some diminution of nitrate action occurs during continuous intravenous administration of NTG or ISDN in unstable angina or acute MI.

Proposed Mechanisms of Tolerance—Old and New

In vitro, vascular tolerance is accompanied by reduced metabolic conversion of nitrates to the pharmacologically active product, NO.[11] This concept is supported by in vivo data in which the amount of exhaled NO decreases as nitrate tolerance develops; with the direct NO donor sodium nitroprusside, tolerance does not develop, nor is there any decrease in exhaled NO.[28] There are a wide variety of hypotheses regarding the pathogenesis of tolerance.[15,29] Many experts believe that there are multiple contributing mechanisms, and no overriding theory is accepted by all.

The **Sulfhydryl Hypothesis** suggests that the process of NO formation from organic nitrates depletes intracellular sulfhydryl groups.[11] When blood vessels are studied in vitro, there is substantial evidence for the sulfhydryl theory; nevertheless, the validity of the sulfhydryl or thiol hypothesis has long been questioned. In isolated vessel experiments, extremely high concentrations of NTG are often used and tolerance may be induced within 1 hour. However, in clinical situations, nanomolar nitrate concentrations are therapeutically effective, whereas the exposure time for nitrate tolerance to develop is at least several hours. Sulfhydryl donors such as acetylcysteine or methionine (indirect sulfhydryl donor) could theoretically counteract tolerance by providing sulfhydryl

Table 5–2 Nitrate Formulations: Dosing Recommendations and Pharmacokinetics*

	Usual Dose (mg)	Onset of Action (min)	Effective Duration of Action
Sublingual NTG	0.3–0.6	2–5	20–30 min
Sublingual ISDN	2.5–10.0	5–20	45–120 min
Buccal NTG	1–3 p.m. or t.i.d.	2–5	30–300 min†
Oral ISDN	10–60 b.i.d. to t.i.d.	15–45	2–6 hr
Oral ISDN-SR	80–120 daily	60–90	10–14 hr
Oral ISMN	20 b.i.d.‡	30–60	3–6 hr
Oral ISMN-SR	60–120 daily	60–90	10–14 hr
NTG ointment	0.5–2.0 inch t.i.d.	15–60	3–8 hr
NTG patch	0.4–0.8 mg/hr§	30–60	8–12 hr

*Higher doses are often required in heart failure.
†Effect persists while tablet intact in buccal cavity.
‡Two daily doses at least 6 hr apart (e.g., 8 o'clock, 3 o'clock).
§Patch should be removed daily for 10-12 hr.
ISDN, isosorbide dinitrate; ISMN, isosorbide mononitrate; NTG, glyceryl trinitrate (nitroglycerin); SR, sustained release.

(-SH) groups within the vascular cells or by forming extracellular nitroso-thiols (RSNO) (see Fig. 5–1), which could enter the vascular cell to directly stimulate guanylate cyclase.[11] In human volunteers, acetylcysteine may provide some protection against nitrate tolerance in veins but not in medium-sized arteries.[28] However, the overall evidence regarding the use of *N*-acetylcysteine to prevent or treat nitrate tolerance remains confusing (see reviews by Boesgaard and coworkers,[30] Fung and Bauer,[11] and Horowitz[15]). In any case, the practical problem of providing exogenous thiols with coadministered nitrates precludes such an approach—except in experimental situations. Although the thiol depletion theory is historically important and well established experimentally, it is no longer considered by many experts to be the primary explanation of nitrate tolerance.[15,29,31,32] However, a new finding does support a rationale for thiols in biotransformation of nitrates to NO (see mitochondrial aldehyde hydrogenase discussion later) (see Fig. 5–2).[9,12-15]

Neurohumoral hypothesis. This construct proposes that nitrate-induced venous dilatation leads to preload reduction and reflex activation of the renin-angiotensin and adrenergic systems that result in compensatory arteriolar vasoconstriction, which may reduce renal perfusion and function.[29,33-37] In congestive heart failure, a prolonged NTG infusion increases plasma catecholamines, endothelin, and renin activity; whereas the levels of vasodilatory atrial natriuretic peptide decrease.[33] Consequently, there also may be impaired salt and water regulation with fluid retention; hematocrit falls during prolonged NTG patch application and body weight increases. Concurrent angiotensin-converting enzyme (ACE) inhibition or angiotensin receptor blocker (ARB) administration may lessen nitrate tolerance in congestive heart failure; at the least, the combination of the two drugs may be clinically effective. However, the benefits of combined ACE inhibitor and ARB nitrate administration have not been consistent; significant improvement with combination therapy has been seen in some, but not all, reports.[29,34-36]

Oxidant stress-vasoconstriction hypothesis. The work of Munzel, Bassenge, Harrison, and their colleagues has suggested an important mechanism for nitrate tolerance.[15,31,32,37-39] These investigators conclusively demonstrated that vascular exposure to organic nitrates results in endothelial cell production of oxygen-free radical species, which increase vascular smooth muscle cell sensitivity to angiotensin II, endothelin, and catecholamines. Experimental damage to, or removal of, the endothelium results in less attenuation of nitrate action.[15,38] These observations link the endothelium as a contributor to attenuated nitrate effects. This hypothesis provides a potential therapeutic role for antioxidants in the reduction of oxidant stress as well as the decreased likelihood for development and maintenance of tolerance. A number of studies have demonstrated a possible role for vitamins C and E, as well as other antioxidants, such as hydralazine, to reduce or prevent tolerance.[39-42] However, Fung has proposed a complex explanation for nitrate tolerance that does not support oxidative stress as the primary mechanism of nitrate tolerance (see below).[43]

Mitochondrial aldehyde hydrogenase (ALDH-2) hypothesis. In 2002, Chen, Zhang, and Stamler proposed that the enzyme mALDH or ALDH-2 is primarily responsible for biotransformation and denitrification of NTG, catalyzing the conversion of NTG to 1,2-glyceryl dinitrate within the mitochondria.[12-15] High concentrations of NTG, as well as inhibitors of ALDH-2, decreased vascular relaxation induced by organic nitrates (i.e., promoted the development of NTG tolerance). The authors suggest that "...build-up of NTG and/or NO byproducts in mitochondria may result in mitochondrial damage and uncoupling of respiration.[13] Furthermore, oxidative stress and reactive oxygen species attenuated NTG biotransformation." Thus, ALDH-2 inhibition is postulated to be a major cause of nitrate tolerance. Subsequently, Munzel and coworkers linked nitrate tolerance with inhibition of ALDH-2 and impairment of NTG metabolism, endothelial dysfunction, and increased mitochondrial production of ROS.[13] These investigators believe "mitochondrial dysfunction plays a key role in evolution of nitrate tolerance." Parker and Gori further evaluate these phenomena in several detailed commentaries.[14,31,32] In 2005, Chen and associates published evidence that the bioconversion by mALDH of clinically relevant concentrations of NTG results in activation of guanylate cyclase, production of cGMP, and vasodilatation.[9] Furthermore, it was shown that inactivation of mALDH occurred with continued exposure to NTG and was an important mechanism for the development of nitrate tolerance.[9] (See earlier comments about controversy regarding mALDH and nitrate tolerance).

Thionitrate oxidation. H.L. Fung, a long-standing contributor to our knowledge of nitrate pharmacotherapeutics, suggests that multiple thiols are important in the bioactivation of nitrates and are involved in the development of nitrate tolerance.[8] He disputes that the mitochondrial aldehyde dehydrogenase hypothesis is the sole contributor to nitrate biotransformation and subsequent nitrate tolerance (personal communication).

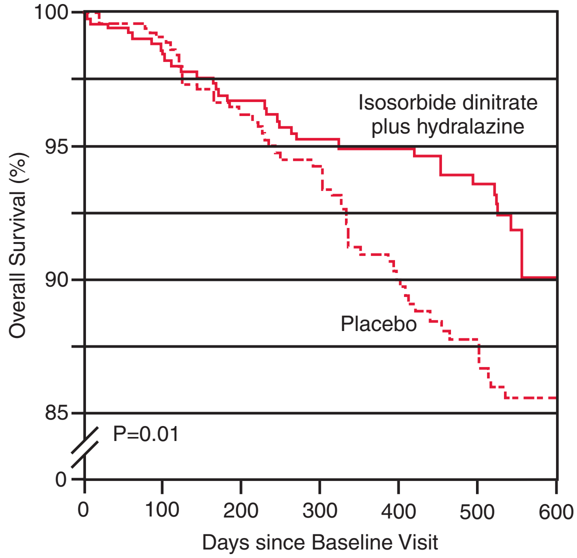
Autonomic nervous system hypothesis. New research suggests an interaction of organic nitrates with the autonomic nervous system (ANS) at both peripheral and central sites. For

instance, NO synthesis in the brain stem inhibits medullary areas that modulate sympathetic outflow; this action is lost in the presence of nitrate tolerance—possibly related to abnormal central nervous system nitric oxide synthase (NOS) activity.[44] "A tolerance-dependent loss of a sympathoinhibitory mechanism might blunt the vasodilatory responses to NO donors in resistance vessels, thus contributing to nitrate tolerance."[45] Increases in brain O_2, as well as angiotensin II, may modulate these alterations. Chronic nitrate therapy may result in increased sympathetic outflow and decreased parasympathetic tone. In a pig model, chronic nitrate administration decreased the number of NO-producing neurons in the brain stem with a loss of inhibitory effects of NO on sympathetic excitability.[44] These phenomena could contribute to nitrate tolerance.

L-Arginine hypothesis. L-arginine, the immediate precursor of NO, is depleted in the presence of nitrate tolerance; this contributes to oxidative stress and uncoupling of NOS, resulting in increased L-arginine requirements and relative L-arginine depletion. There is a related reduction in stores of tetrahydrobiopterin (BH_4), a situation that further contributes to impaired NO availability and uncoupling of NOS.[15,31,32] Replenishment of BH_4 by folic acid increases NOS but may not reverse tolerance. Peroxynitrate can oxidize BH_4, increasing NOS but also oxidative anions. Folate replacement increases BH_4 stores and can prevent or reverse nitrate tolerance, independent of the antioxidant effects of folic acid.[46] These phenomena may be characterized as injury to the arginine transport system caused by exogenous nitrates. Considerable data suggest that folate or L-arginine supplementation results in sustained NOS function and the prevention or amelioration of nitrate tolerance.[42,46-49]

The nitrate-hydralazine relationship. Experimentally, concurrent hydralazine administration during nitrate therapy prevents hemodynamic tolerance in heart failure.[22-24,50] Hydralazine also helps to maintain renal blood flow when it is coadministered with ISDN.[22] It is now recognized that hydralazine may act in part as an antioxidant, reducing oxidant stress and its adverse effects on tolerance.[24,50] Thus, the protective role of hydralazine may be to quench oxidative stress in the presence of organic nitrates. A number of studies have combined isosorbide dinitrate (ISDN) and hydralazine (H) and demonstrated positive results without tolerance in congestive heart failure (CHF) subjects. In the first Vasodilator Heart Failure Trial (V-HeFT I), this combination was effective in reducing mortality compared with placebo and the α-blocker prazosin.[21] That study was the first to demonstrate a decrease in mortality in any CHF drug trial. In retrospective analyses of both V-HeFT-I and V-HeFT-II, the combination of ISDN and hydralazine was noted to be more effective in blacks than in whites.[51] Other data suggest differences in endothelial vasodilator responses between black and white subjects.[52]

The African-American Heart Failure Trial (A-HeFT), completed in 2004, was designed in part because of the positive data with an ISDN-H combination.[26] The A-HeFT rationale capitalized on the concept of increased NO availability by provision of both ISDN and hydralazine to African-American heart failure patients. It has been suggested that blacks have decreased endothelial vasomotor responses, decreased nitric oxide (NO) responsiveness, and a less active renin angiotensin system than whites.[51,52] The A-HeFT study enrolled 1005 black subjects with class III or IV heart failure or left ventricular enlargement, who were followed for a mean of 10 months.[26] Mortality was reduced by 43% in the active treatment cohort when compared with placebo subjects, along with a comparable composite endpoint reduction (first rehospitalization and quality of life measurements). The differences between the drug combination and placebo were robust (Fig. 5–3).



No. at Risk

Placebo	532	466	401	340	285	232	24
Isosorbide dinitrate plus hydralazine	518	463	407	359	313	251	13

Figure 5–3 **Kaplan-Meier estimates of overall survival.** The A-HeFT investigators reported that a fixed dose of isosorbide dinitrate plus hydralazine increased survival when added to standard therapy in black patients with heart failure. (Redrawn from Taylor AL, Ziesche S, Yancy C, et al., for the African-American Heart Failure Trial Investigators: Combination of isosorbide dinitrate and hydralazine in blacks with heart failure. N Engl J Med 2004;351:2052.)

Of particular interest is the possibility that hydralazine, known to be a free radical scavenger, may have prolonged the physiological activity of ISDN, allowing for protracted hemodynamic benefits with less or no nitrate tolerance during the course of the trial. The authors suggest that hydralazine provided "protection against the degradation of nitric oxide induced by oxidative stress,"[26] although specific direct evidence supporting this hypothesis is not available. Considerable experimental data confirm that decreases in NO availability and endothelial vasomotor dysfunction are common in models of heart failure, with a host of adverse consequences related to impaired cardiac muscle function. Furthermore, the concept that hydralazine prolongs the duration of nitrate efficacy, attenuating or even preventing nitrate tolerance, is critical to the design of A-HeFT. The strongly positive A-HeFT results, although not definitive, appear to support the "hydralazine is an antioxidant" hypothesis, as suggested by Munzel and colleagues in 1996.[50]

In June 2005, the United States Food and Drug Administration approved an ISDN-hydralazine combination pill (BiDil) for use in the United States. It is likely that this combination will subsequently be tested in a variety of clinical conditions. If, as remains unproven as of this writing, a free radical scavenger such as hydralazine can truly sustain nitrate action without adverse sequelae, nitrates will again be in the forefront of cardiovascular therapy.

Several outstanding reviews of nitrate bioactivation and nitrate tolerance are recommended to the interested reader.[14,15,31,32,46] It is clear that the nitrate tolerance story remains incomplete and unsolved. The thiol and oxidative stress theories are compelling. Interactions between organic nitrates, oxidative stress, and thiols of various origins, appear to be pivotal, but we still have far to go to understand and unravel these complex phenomena.

Can Nitrates Be Harmful?

It has long been assumed that therapy with organic nitrates is beneficial, or at least neutral, in the presence of nitrate tolerance. Coronary artery vasoconstriction following acetylcholine administration during coronary angiography after NTG transdermal patch removal has been documented.[53] Rebound symptoms of nocturnal angina have been noted in several studies during the patch-off period with intermittent NTG patches therapy in subjects with angina.[54] A retrospective data analysis from Japan[55] and a post hoc analysis of two randomized clinical trials[56] suggest that long-term nitrate therapy in patients with coronary disease may be associated with adverse clinical outcomes. These provocative data, if confirmed, could explain in part why nitrates were not shown to reduce morbidity and mortality rates in the two large post-MI clinical trials, ISIS-4 and GISSI-4. As discussed, data from nitrate tolerance studies confirm increased oxidative stress, decreased biotransformation of NTG, decreased eNOS activity, and endothelial dysfunction in the presence of nitrate administration. These phenomena suggest that nitrate tolerance may not be neutral or benign.

Prevention of Tolerance

The use of eccentric dosing with short-acting oral nitrates (ISMN, ISDN) (e.g., two doses per day administered 7 to 8 hours apart) is the simplest and most reliable method to avoid tolerance.[11,29,57-59] Many studies in patients with effort angina show that tolerance can be avoided or minimized with an interval dosing approach. A single daily dose of a long-acting oral nitrate (ISDN, 5-ISMN) is also effective in preventing tolerance, presumably because this allows for rising and falling plasma drug levels. Nitroglycerin patch administration requires an intermittent dosing strategy of 12 to 14 hours on and 10 to 24 hours off each day. Even when nitrate tolerance is established, sublingual nitrates retain their therapeutic effect. Dose escalation with nitrates may be useful in avoiding or overcoming nitrate tolerance in patients with congestive heart failure and coronary syndromes.[60]

Nitrate Cross-tolerance

Tolerance to long-acting nitrates may also result in cross-tolerance to short-acting nitrates, and vice versa, as shown for forearm capacitance vessels, coronary artery diameter, and exercise tolerance performance during intravenous NTG therapy.[5]

Tolerance versus Resistance

High intravenous NTG doses (in excess of 200 μg/min) or very large doses of ISDN occasionally have no hemodynamic effect, even when administered in the absence of earlier nitrate therapy. This phenomenon has been called *nitrate resistance* and has been well documented in congestive heart failure.[15,60,61] Intense renin-angiotensin activation and accelerated tolerance induction may contribute to nitrate resistance, which is generally seen only in severe biventricular heart failure.

Side Effects of Nitrates

Headaches are the most common adverse effect of nitrate therapy; they often lead to loss of patient acceptance of the prescribed nitrates. A decrease in headaches over time is common and may reflect in part subjective adaptation, arterial tolerance, or both.

Hypotension (e.g., systolic blood pressure of less than 100 mm Hg systolic) occurs in about 10% of patients receiving low-dose intravenous NTG and can be reversed by discontinuing the infusion or reducing the rate. With oral nitrates, symptomatic hypotension seldom occurs without other therapies, such as β-adrenergic antagonists or dihydropyridine calcium blockers. Reduction of the dose of either drug or a change of agent should be considered in such cases. Many individuals experience dizziness, presyncope, or even syncope on initial exposure to sublingual NTG.

Other occasional adverse effects include hypoxemia in patients with chronic lung disease due to increased ventilation-perfusion mismatch. Prolonged high-dose intravenous NTG therapy has rarely caused methemoglobinemia with cyanosis.

Nitrates and Phosphodiesterase-5 Inhibitors

Phosphodiesterase-5 (PDE-5) inhibitors are used to treat sexual dysfunction in men; they include sildenafil, tadalafil, and valdenafil.[62] These agents improve penile erectile function by increasing smooth muscle relaxation which results in engorgement of the corpus cavernosum, venous compression, and sustained penile rigidity. The mechanism of action—prolonged PDE-5 inhibition—allows for greater and longer cGMP action, thus enhancing male sexual function. The three drugs available have demonstrated a high level of improvement in men with erectile dysfunction (ED) of many causes.

The risk of an adverse pharmacologic interaction of PD5 agents in the presence of organic nitrates is the development of major hypotension that results from increased NO availability, coupled with decreased cGMP degradation. Thus, nitrates, including sublingual and transdermal nitroglycerin, are contraindicated during exposure to the PDE-5 inhibitors. The duration of time from ingestion of a PDE-5 inhibitor during which nitrates are precluded is variable, and depends on the drug used. For the short-acting agents—sildenafil and valdenafil—the "no nitrate" time frame is 24 hours, but for the longer acting tadalafil, this period is up to 48 hours, during which time concomitant use of a nitrate and the PDE-5 inhibitor is clearly contraindicated.[60]

Combination Therapy for Anginal Syndromes

Although abundant clinical experience supports the practice of combining nitrates with β-blockers and/or CCBs in the therapy of anginal syndromes, there is no evidence that the addition of nitrates to the use of other antianginal agents decreases morbidity or mortality rates.[58] Nitrate-dosing regimens used in most older studies have often been subsequently shown to cause tolerance.

The combination of β-blockade and nitrates is standard in the therapy of angina. β-blockers decrease heart rate and arterial blood pressure and may increase left ventricular cavity size; nitrates act primarily by reducing preload and, to a lesser degree, afterload, and they often result in tachycardia and a smaller heart. There do not appear to be pharmacokinetic interactions between these two classes of drugs.

CCBs and nitrates are also often combined, yet there is relatively little clinical trial evidence of an increased antianginal effect. When a nitrate is used, the addition of a nondihydropyridine (non-DHP) (e.g., verapamil, diltiazem) is preferable to the nifedipine-like DHPs because of the significant afterload reduction induced by the short-acting DHPs. The hemodynamic actions of verapamil and diltiazem resemble those of β-blockers, with a negative inotropic effect and a modest slowing of heart rate, whereas the short-acting DHPs may reflexively increase heart rate. The recommended combinations for chronic stable angina are a nitrate plus a β-blocker, a nitrate plus a rate-slowing CCB, or a β-blocker plus a DHP CCB.[58,59]

Triple therapy with nitrates, β-blockers, and CCBs is frequently used in subjects with continuing angina. Nonetheless, such an approach carries the risk of excess hypotension, as well as potential adverse interactions between a β-blocker and a rate-slowing CCB (e.g., additive negative inotropic effects, additive sinoatrial, atrioventricular nodal inhibition with verapamil or diltiazem). Furthermore, no clinical trial data are available to support the efficacy of a three-drug regimen.

Direct Nitric Oxide Donors: Sodium Nitroprusside

SNP is the prototype of a direct NO donor, releasing NO into the vascular smooth muscle cell without requiring enzymatic conversion (see Fig. 5–1). Thus, SNP vasodilates all vessels, both venous and arterial, and the microcirculation. Perhaps because this agent is a direct NO donor, tolerance has not been documented with its use. SNP vasodilates the small coronary arterioles (less than 100 mm in diameter), which could induce a coronary steal phenomenon, in the setting of coronary atherosclerosis. In an important study, Mann and coworkers[6] showed that when SNP was administered to patients with coronary artery disease, regional myocardial blood flow decreased significantly. In contrast, after sublingual NTG administration, regional flow increased. For that reason, SNP is not the drug of choice when blood pressure reduction is required in the presence of active myocardial ischemia. Nonetheless, the drug is appropriate in severe or acute congestive heart failure requiring intravenous afterload and preload reduction in the absence of ongoing myocardial ischemia.

SNP is converted to cyanomethemoglobin and free cyanide in red blood cells; the free cyanide is further converted to thiocyanate in the liver and cleared by the kidneys with a half-life of 7 days. Thus, cyanide may accumulate with prolonged high doses of SNP and produce lactic acidosis. Inactivation of cyanide by the liver may be limited by the availability of thiol groups, and administration of thiosulfate can protect against SNP toxicity.[63]

SNP remains useful for the acute management of hypertensive emergencies and severe congestive heart failure. It is administered only intravenously, the solution must be protected from light, and tissue extravasation should be avoided. Blood pressure monitoring with either an indwelling arterial catheter or automatic noninvasive system is required because of the potential for a rapid fall in blood pressure.

CALCIUM CHANNEL BLOCKERS

CCBs are agents that inhibit several specific calcium-dependent functions in the cardiovascular system. By decreasing vascular smooth muscle contraction and tone, they produce peripheral and coronary vasodilatation. The non-DHPs have a negative inotropic effect, which is an undesired action if it becomes excessive. Certain CCBs (e.g., verapamil, diltiazem) inhibit calcium-dependent SA and AV nodal conduction. The CCBs are approved for use in hypertension, angina pectoris, and acute supraventricular tachycardias. In the United States, the most commonly used available CCBs are diltiazem, verapamil, nifedipine, amlodipine, and felodipine. Bepridil, isradipine, and nicardipine are available but are used relatively infrequently; nimodipine is usually used only for subarachnoid hemorrhage or ruptured cerebral aneurysm.

Fundamental Mechanisms of Calcium Channel Blockers

Calcium Channel as Site of Action

CCBs interfere with the entry of Ca^{2+} into cells through voltage-dependent L- and T-type calcium channels.[64] The major cardiovascular sites of action are (1) vascular smooth muscle cells, (2) cardiac myocytes, and (3) SA and AV nodal cells. By binding to specific sites, known as subunits, in the proteins of the calcium channel, these agents are able to diminish the degree to which the calcium channel pores open in response to voltage depolarization (Fig. 5–4).

Molecular Structure. The calcium channel consists of four high-molecular-weight subunits, named α1, α2, β, and γ. Of these, it is the α1 subunit that contains the calcium channel pores and the binding sites for CCBs. The subunits have a complex structure with four major domains (see Fig. 5–4), each with six transmembrane units.[65] The calcium channel pores exist between the fifth and sixth units. The voltage sensor is located near the fourth transmembrane unit of each domain.

There are two important regulatory aspects of calcium channel blockade. First, when cyclic adenosine monophosphate (cAMP) activates protein kinase A to phosphorylate the calcium channel, there are a number of phosphorylation sites on the COOH-terminal portion of each of the α1 subunits. Such phosphorylation allows the channel to persist in a more open state. Second, the β subunit binds to the cytoplasmic link between the domains I and II of the γ1 subunit and thereby enhances calcium channel opening.[64]

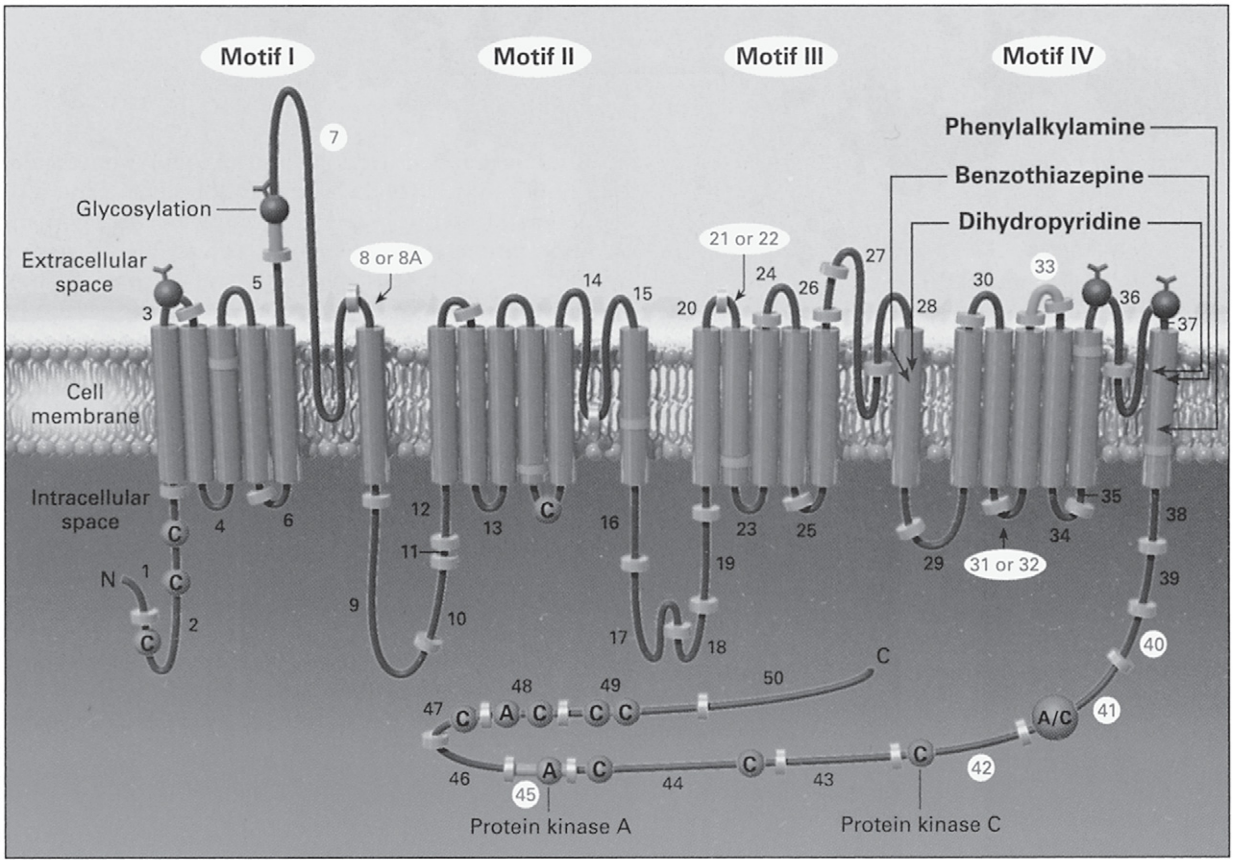


Figure 5–4 (*See also Color Plate 5–4*). **Proposed arrangement of the polypeptide chain of the channel-forming α_{12} subunit of the L-type calcium channel in humans.** There are four repetitive motifs (I, II, III, and IV), and each consists of six putative transmembrane segments. Both the N terminal and the C terminal point to the cytoplasm. Rings separate the segments encoded by numbered exons. The transmembrane segments encoded by alternative exons 8 or 8A, 21, or 22, and 31 or 32 are shown. Sequences encoded by invariant exons 7, 33, and 45, which are subject to constitutive splicing, are also shown. Exons 40, 41, and 42 are subject to alternative splicing. Putative sites of glycosylation and of phosphorylation involving protein kinase C (C) and protein kinase A (A) are shown, as are the discrete binding areas of the three types of calcium antagonists—phenylalkylamine (verapamil-like), benzothiazepine (diltiazem-like), and dihydropyridine (nifedipine-like). (From Abernethy DR, Schwartz JB: Calcium-antagonist drugs. N Engl J Med 1999;341:1448.)

Drug-Binding Sites. There are at least three binding sites for these drugs, commonly known as the V, or phenylalkylamine; N, or DHP; and D, or benzothiazepine, binding sites (identified by the prototype agents verapamil, nifedipine, and diltiazem, respectively). The N-binding site is also termed the DHP site, to which all DHPs are thought to bind. Each of the different agents binds to specified sites on various domains, and none binds to all of the pores in all the domains. Thus, calcium channel blockade can never be complete.

Calcium Channels: L and T Types

The most important property of the CCBs is to selectively inhibit the inward flow of charge-bearing Ca^{2+} when the calcium channel becomes permeable, or "open." There are at least two types of calcium channels relevant to the treatment of cardiovascular disorders: the L and T types. The major calcium channel related to pharmacologic antagonism, the voltage-gated L-type (long-acting, slowly activating) channel, is blocked by all available CCBs. The function of the L-type channel is to allow entry of sufficient Ca^{2+} for initiation of contraction by calcium-induced intracellular calcium release from the sarcoplasmic reticulum.

The T-type (transient) channel appears at more negative potentials than the L type and probably plays an important role in the initial depolarization of SA and AV nodal tissue. The L-type calcium channel is found in vascular smooth muscle, nonvascular smooth muscle in many tissues, and a number of noncontractile tissues. Blockade of the L-type channel is responsible for the pharmacologic actions of the available CCBs.

Pharmacologic Properties of Calcium Channel Blockers

Pharmacodynamic Effects

Despite their structural diversity and binding differences, CCBs display many common important pharmacologic actions. However, there are significant differences between the sites of action of the DHPs and non-DHPs (Table 5–3).

Table 5–3 Vasodilator Potency, and Inotropic, Chronotropic, and Dromotropic Effects of Calcium Channel Blockers on the Heart

	Amlodipine	Diltiazem	Nifedipine	Verapamil
Heart rate	↑/0	↓	↓	↓
Sinoatrial node conduction	0	↓↓	0	↓
Atrioventricular node conduction	0	↓	0	↓
Myocardial contractility	↓/0	↓	↓/0	↓↓
Neurohormonal activation	↑/0	↑	↑	↑
Vascular dilatation	↑↑	↑	↑↑	↑
Coronary flow	↑	↑	↑	↑

↓ = decrease; 0 = no change; ↑ = increase.
Adapted from Abernethy DR: Pharmacologic and pharmacokinetic profile of mibefradil, a T- and L-type calcium channel antagonist. Am J Cardiol 1997;80:4C-11C, with permission from Excerpta Medica Inc.

Major Cardiovascular Actions of Calcium Channel Blockers

1. *Vasodilatation*: This effect is more marked in arterial and arteriolar vessels than on veins and includes the coronary vasculature; veins do not appreciably dilate with CCBs.
2. *Negative chronotropic and dromotropic effects* on the SA and AV nodal conducting tissue (non-DHP agents only)
3. *Negative inotropic effect* on myocardial cells; in the case of DHPs, this effect may be offset by reflex adrenergic stimulation after peripheral vasodilatation.

Classification of Calcium Channel Blockers

The differing pharmacodynamic effects of various CCBs accounts for the classification of the CCBs. All the DHPs bind to the same sites on the α1 subunit and exert a greater Ca^{2+} inhibitory effect on vascular smooth muscle than on the myocardium, which explains their common property of vascular selectivity. Thus, their major hemodynamic and therapeutic effect is peripheral and coronary vasodilatation.

Nifedipine is the prototypical DHP. The fast-acting capsular form produces rapid vasodilatation, alleviates hypertension, and terminates attacks of coronary spasm. However, the brisk peripheral vasodilatation produced by this formulation may result in significant hypotension and reflex adrenergic activation, often causing tachycardia and stimulation of the sympathetic and renin-angiotensin systems. The introduction of truly long-acting DHP compounds, such as amlodipine or sustained-release formulations of nifedipine, felodipine, or isradipine, has resulted in substantially fewer symptoms owing to vasodilatory side effects. It is a commonly held belief that the short-acting DHPs, particularly nifedipine, account for the majority of presumed negative or adverse clinical results in many older trials.[64,66] The second-generation DHPs are distinguished by a longer half-life, as in the case of amlodipine, or by a greater vascular selectivity.

The non-DHPs verapamil and diltiazem, although each binding to different sites on the α1 subunit, have many properties in common. Both act on nodal (SA and AV) tissue and are therapeutically effective in supraventricular tachycardias. Both decrease the sinus discharge rate. These drugs inhibit myocardial contractility more than the DHPs (i.e., are less vascular selective). Both verapamil and diltiazem have greater effects on the AV node than on the SA node; the explanation for this may relate to frequency dependence. Thus, there is better access to the binding sites when the calcium channel pore is open. During supraventricular tachycardia, the calcium channel of the AV node opens more frequently, so the CCB binds more avidly and, hence, more specifically inhibits the AV node to interrupt the reentry circuit.

Regarding side effects, because non-DHPs are less active on vascular smooth muscle, they produce fewer vasodilatory adverse reactions than the DHPs. Sinus tachycardia is uncommon, in part because of the inhibitory effects on the SA node. High-degree AV block is a risk with preexisting AV nodal disease or during cotherapy with other AV node-depressant drugs, such as β-blockers. Non-DHPs have a more marked depressive effect on ventricular function than DHPs. Constipation occurs as a side effect with verapamil but seldom with diltiazem; the latter may cause peripheral edema.

Vascular Selectivity

The cellular mechanism of vascular smooth muscle contraction differs from that of the myocardium. Although smooth muscle contraction is ultimately calcium dependent, it is the myosin light-chain kinase that is activated by calcium-calmodulin. In the case of the human myocardium, Godfraind and associates[67] proposed that the ratios of vasodilatation to negative inotropy for the prototype CCBs were 10:1 for nifedipine, 1:1 for diltiazem, and 1:1 for verapamil. Other DHP compounds have even greater vascular selectivity, up to 1000:1. In terms of clinical use, these observations provide the basis for considering a clinical division of the CCBs into two groups: the DHPs (i.e., nifedipine and its analogs) and the non-DHPs (e.g., verapamil, diltiazem, and their derivatives).

Noncardiovascular Effects

Although highly active on vascular smooth muscle, CCBs have little or no effect on other smooth muscle throughout the body, such as that of the bronchi, gut, or genitourinary tract. These agents may relax uterine smooth muscle and have been used in preterm contractions. It is generally recommended that they be stopped before delivery. This probably reflects variations between tissues in either the structure or function of their calcium channels. Also crucial to the therapeutic applicability of CCBs is the fact that skeletal muscle does not respond to conventional CCBs. As a result, skeletal muscle weakness is not a side effect of CCB. In skeletal muscle,

Table 5–4 Selected Characteristics of Trials of Calcium Channel Blockers

Study	Agents Used	No. of Patients Enrolled	Patient Characteristics
ALLHAT	Amlodipine vs. chlorthalidone vs. lisinopril	33,357	Hypertension and one risk factor for coronary artery disease
INVEST	Verapamil slow-release ± trandolapril ± hydrochlorothiazide vs. atenolol ± hydrochlorothiazide ± trandolapril	22,576	Hypertension and coronary artery disease
CONVINCE	Extended-release verapamil vs. atenolol or hydrochlorothiazide	16,602	Hypertension and one risk factor for coronary artery disease
NORDIL	Diltiazem vs. diuretics + β-blockers	10,881	Hypertension
STOP-2	Felodipine or isradipine vs. conventional antihypertensive agents	6614	Hypertension
INSIGHT	Nifedipine gastrointestinal therapeutic system vs. hydrochlorothiazide + amiloride	6321	Hypertension and one risk factor for coronary artery disease
VHAS	Verapamil vs. chlorthalidone	1414	Hypertension
MIDAS	Isradipine vs. hydrochlorothiazide	883	Hypertension
ABCD	Nisoldipine vs. enalapril	470	Hypertension and diabetes mellitus
NICS-EH	Nicardipine vs. trichlormethiazide	429	Hypertension and age >60 years
FACET	Amlodipine vs. fosinopril	380	Hypertension and diabetes mellitus
CASTEL	Nifedipine vs. clonidine or atenolol + chlorthalidone	351	Hypertension and age >65 years

ABCD: Appropriate Blood Pressure Control in Diabetes; ALLHAT: Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial; CASTEL: Cardiovascular Study in the Elderly; CONVINCE: Controlled Onset Verapamil Investigation of Cardiovascular Endpoints; FACET: Fosinopril versus Amlodipine Cardiovascular Events Trial; INSIGHT: International Nifedipine Gastrointestinal Therapeutic System study—Intervention as a Goal in Hypertension Treatment; INVEST: International Verapamil Slow-Release/Trandolapril Study; MIDAS: Multicenter Isradipine Diuretic Atherosclerosis Study; NICS-EH: National Intervention Cooperative Study in Elderly Hypertensives; NORDIL: Nordic Diltiazem; STOP: Swedish Trial in Old Patients with Hypertension; VHAS: Verapamil in Hypertension and Atherosclerosis Study.

depolarization-activated calcium release from the sarcoplasmic reticulum is the principal source of the myoplasmic calcium rise. Thus, only the myocardium, and not skeletal muscle, responds to calcium entry through the voltage-dependent calcium channels, and the myocardium, but not skeletal muscle, has its rise in contractile calcium inhibited by CCBs.

Pharmacokinetics

From the point of view of drug interactions, all of the CCBs are metabolized in the liver by an enzyme system that is inhibited by cimetidine, azole antifungals, and hepatic dysfunction and increased in activity by phenytoin and phenobarbital. (See Appendix 1 for dosage information and drug interactions.)

Major Indications for Calcium Channel Blockers

Systemic Hypertension

The various CCBs act on peripheral arterioles. They are effective antihypertensive agents in all ethnic and age groups. All DHPs decrease peripheral vascular resistance and appear to have an additional ill-understood diuretic effect. Verapamil and diltiazem are less powerful vasodilators; some believe that their negative inotropic effect may contribute to their antihypertensive mechanism. Table 5–4 lists some major hypertension trials in which a CCB was used.

Angina Pectoris

Although the antianginal mechanisms of the different types of CCBs differ somewhat, these drugs share some properties: (1) coronary vasodilatation, especially in relation to exercise-induced coronary constriction, and (2) afterload reduction due to decreased blood pressure. In the case of verapamil and diltiazem, it is possible that slowing of the sinus node, with a decrease in nonmaximal exercise heart rate, and the negative inotropic effect, may contribute to decreased myocardial work.

As coronary dilators, the CCBs have a site of action on the coronary tree different from that of the nitrates. The CCBs act more specifically on the smaller coronary resistance vessels, where the tone is higher and the calcium inhibitory effect is more marked. CCBs are particularly effective in those types of angina caused by or exacerbated by coronary spasm or constriction, such as Prinzmetal angina or cold-induced angina. An overview of a large number of angina drug trials concluded that the CCBs have a very similar clinical efficacy to β-blockers.[68]

Supraventricular Tachycardia

Through their inhibitory effect on the AV node, verapamil and diltiazem interrupt the reentry circuit in supraventricular

tachycardias and are useful in terminating those arrhythmias. They are also effective in slowing the ventricular response in atrial fibrillation and may be used in chronic atrial fibrillation; the DHPs are ineffective for these arrhythmias because of minimal effects on the SA and AV node.

Postinfarct Protection

Verapamil is licensed in Scandinavian countries for postinfarct protection in patients in whom β-blockers are contraindicated. In the Danish Verapamil Infarction Trials DAVIT-1 and DAVIT-2, a modest protective benefit against death and cardiac ischemic events in post-MI subjects was documented in subjects without a history of heart failure.[69] Diltiazem has been shown to be beneficial in post-MI subjects with relatively normal LV function and no heart failure.[70] A short-term (2-week) study in non–Q-wave MI patients with high-dose diltiazem reduced the rates of recurrent ischemia and infarction.[70]

Specific Calcium Channel Blockers

Verapamil

After peripheral vasodilatation induced by verapamil, the cardiac output and LV ejection fraction do not increase as much as they do with the DHPs, probably owing to the negative inotropic effect and depression of contractility of verapamil.

Pharmacokinetics

The elimination half-life of standard verapamil tablets is usually 3 to 7 hours, but it increases significantly during long-term administration, as well as in patients with liver or renal insufficiency. In significant hepatic dysfunction, the dose of verapamil should be decreased by 50% to 75%. In significant renal dysfunction, such as a creatinine clearance of less than 30 mL/min, the dose should be reduced by 50%. Bioavailability is only 10% to 20% (high first-pass liver metabolism). The parent compound and the active hepatic metabolite norverapamil are excreted 75% by the kidneys and 25% by the gastrointestinal tract. Verapamil is 87% to 93% protein bound.

Dose

Oral Preparations. The usual dosage of the standard preparation is 80 to 120 mg t.i.d.. During long-term oral dosing, less frequent daily doses are needed (norverapamil metabolites). Slow-release preparations (240 to 480 mg daily) are administered once or twice daily.

Intravenous Use. For supraventricular reentry tachycardias, a bolus of 5 to 10 mg (0.1 to 0.15 mg/kg) can be administered over 2 minutes and repeated 15 to 20 minutes later if needed. After successful administration, the dose may be stopped or continued at 0.005 mg/kg/min for about 30 to 60 minutes, decreasing thereafter. When used for control of the ventricular rate in atrial fibrillation, verapamil may be administered at 0.005 mg/kg/min, increasing as needed, or as an intravenous bolus of 5 mg followed by a second bolus of 10 mg if needed. In the presence of myocardial disease or interacting drugs, a very low dosage (0.0001 mg/kg/min) may be infused and titrated upward against the ventricular response. However, safer AV slowing agents are available for patients with impaired LV systolic function (digoxin, adenosine).

Side Effects

Side effects include headaches, facial flushing, dizziness, and ankle edema—all lower in frequency than with the DHPs. Constipation occurs in up to one third of patients who receive verapamil. The negative inotropic effect of verapamil may precipitate or exacerbate congestive heart failure. When intravenous verapamil is used, the risk of hypotension is increased if the patient is receiving β-blockers or other vasodilators or has depressed cardiac function.

Contraindications

Sick sinus syndrome and preexisting AV nodal disease are relative contraindications to intravenous and oral verapamil. The effective use of oral verapamil preparations in these conditions may require a pacemaker. In the Wolff-Parkinson-White syndrome with atrial fibrillation, intravenous verapamil may promote antegrade conduction of impulses down the bypass tract, with a risk of very rapid atrial fibrillation and even ventricular fibrillation. In a wide QRS complex ventricular tachycardia, verapamil is contraindicated because the combined negative inotropic and peripheral vasodilatory effects can be fatal; furthermore, verapamil is unlikely to terminate a ventricular arrhythmia. Verapamil should not be used when there is moderate or severe LV dysfunction or severe hypotension.

Pregnancy. Category C (use only if potential benefit justifies the potential risk to fetus); no well-controlled trials are available.

Diltiazem

Diltiazem is used for the same spectrum of cardiovascular disease as verapamil: hypertension, angina pectoris, prevention of AV nodal reentry, tachycardias, and rate control in acute and chronic atrial fibrillation. The side effect profile is similar except that constipation is much less common.

Pharmacokinetics

More than 90% of oral diltiazem is absorbed, with approximately 45% bioavailability (first-pass hepatic metabolism). The onset of action is within 15 to 30 minutes; peak effects occur at 1 to 2 hours. The elimination half-life is 4 to 7 hours. Protein binding is 80% to 90%. Diltiazem is acetylated in the liver to the active metabolite desacetyl diltiazem (40% of the activity of the parent compound), which accumulates during long-term therapy. Only 35% of diltiazem is excreted by the kidneys, and 65% is excreted by the gastrointestinal tract.

Dose

The standard oral dose of short-acting diltiazem is 120 to 360 mg daily, in three or four divided daily doses. The slow-release preparations are administered once or twice daily. Generic diltiazem is available. Intravenous diltiazem (approved for arrhythmias) is administered as 0.25 mg/kg over 2 minutes with electrocardiographic and blood pressure monitoring; if the response is inadequate, the dose is then repeated as 0.35 mg/kg in 15 to 20 minutes. Acute loading therapy may be followed by an infusion of 5 to 15 mg/hr.

Side Effects

Side effects are few and limited to headaches, dizziness, and ankle edema in 6% to 10% of patients. The extended or slow-release preparations appear to have a side effect profile similar to that of placebo. Sinus bradycardia and first-degree AV nodal block (or higher) may be produced by diltiazem. It is important to avoid or reduce dosing in subjects with SA or AV nodal disease. In heart failure with significant LV dysfunction (e.g., ejection fraction of less than 35%), this drug can be hazardous. Exfoliative dermatitis and skin rash occur occasionally. The side effects of intravenous diltiazem resemble those of intravenous verapamil.

Contraindications

Contraindications are similar to those of verapamil: preexisting depression of the SA or AV node, hypotension, low ejection fraction, heart failure, and atrial fibrillation associated with the Wolff-Parkinson-White syndrome. LV failure ejection fraction of less than 40% after MI is a clear contraindication.[68]

Pregnancy. Category C (use only if potential benefit justifies the potential risk to fetus); no well-controlled trials are available.

Dihydropyridines

The major therapeutic action of the DHPs is arterial and arteriolar dilatation, which is responsible for their efficacy in hypertension and angina pectoris, as well as Prinzmetal or variant angina and Raynaud's phenomenon. Direct negative inotropic effects of the DHP drugs are minimal. Amlodipine is the CCB of choice in patients with severely depressed LV function because it does not decrease LV contractility at standard doses. There is no clinically significant evidence of the effect of DHP on either the SA or the AV node; these agents are not effective in supraventricular arrhythmias. They may be more readily combined with β-blockers in hypertension or angina pectoris than the rate-slowing CCBs, with less concern about depression of the SA and AV nodes.

First-Generation Dihydropyridines

Oral nifedipine is the prototypical dihydropyridine. It is rapidly absorbed with peak blood levels in 20 to 45 minutes. and a duration of action of 4 to 8 hours. Because of this short half-life and difficulty controlling the degree of blood pressure lowering, it is rarely used in its short-acting form. Slow-release forms are currently available and are preferred by some physicians. The dose for the slow-release form is 30 to 90 mg once a day.

Contraindications and Cautions

The short-acting forms are generally contraindicated.

Side Effects

Because DHPs have no SA or AV effects, reflex tachycardia may occur if excessive blood pressure lowering occurs. Headache can occur with any of the CCBs, but they occur more frequently with the first generation dihydropyridines.

Pregnancy. Category C (use only if potential benefit justifies the potential risk to fetus); no well-controlled trials are available.

Second-Generation Calcium Channel Blockers

Theoretically, the more vascular selective DHPs, such as felodipine, isradipine, amlodipine, and nicardipine, should be safer than nifedipine in the management of angina or hypertension—particularly when there is impairment of LV function. These drugs may produce adverse effects in patients with congestive heart failure, although felodipine and amlodipine appear to be quite safe in patients with depressed LV function.[71,72] In fact, amlodipine has been shown to have no adverse effect (and no benefit) compared with placebo in the PRAISE and PRAISE-2 heart failure trials. These compounds are the DHPs of choice in subjects with decreased LV function or a history of heart failure.

Although amlodipine is no more vascular selective than nifedipine, it has unusual pharmacokinetics, including slow onset and offset of binding to the calcium channel site and a prolonged elimination half-life.[73] The doses, pharmacokinetics, side effects, and interactions of these agents are shown in Appendix 1. Based on these pharmacokinetic-characteristics and new extensive experience with this agent in both angina and antihypertensive studies, amlodipine has become the dihydropyridine of choice by most physicians in the Western Hemisphere.

Drug Interactions of Calcium Channel Blockers

β-Blockers. Verapamil and diltiazem contribute to SA or AV nodal, as well as myocardial, depression or may interact via hepatic mechanisms with those β-blockers metabolized by the liver, such as propranolol and metoprolol. Although these drugs have been successfully combined with β-blockade in the therapy of angina or hypertension, clinicians should monitor patients for possible serious adverse effects when a rate-slowing CCB is combined with a β-blocker.

Digoxin. Verapamil increases blood digoxin levels by decreasing the renal excretion of digoxin. Enhancement of AV nodal block can be serious and even fatal when intravenous verapamil is administered to patients with digitalis intoxication.

Diltiazem. In general, drug interactions with diltiazem are similar to those of verapamil. Diltiazem has a slight or negligible effect on blood digoxin levels. Although diltiazem may be cautiously combined with β-blockade, the combination appears to be no more effective in some studies than high-dose diltiazem itself. Cimetidine may increase diltiazem bioavailability, resulting in a 50% to 60% increase in plasma diltiazem levels.

Dihydropyridines. The combination of DHPs with β-blockers is safer than that with non-DHP CCBs. When there is LV depression, the added negative inotropic effects of a β-blocker and DHP may precipitate overt heart failure, but this is unusual; amlodipine or felodipine is the CCB of choice in such individuals.

Calcium Channel Blockers: The "Safety" Controversy

Beginning in 1995, a question about the safety of all calcium channel blockers was raised when a retrospective analysis of

the short-acting form of nifedipine appeared to increase heart attacks in acute coronary syndrome patients, but the data were grouped with all CCBs. As prospective trials did not confirm these fears and physicians gained experience with the slow release non-dihydropyridines and long-acting dihydropyridines such as amlodipine, this issue gradually died. In fact, several antihypertensive trials have established the safety and benefit of these agents.[64,66]

Two completed hypertension trials with dihydropyridines and amlodipine have finally established the safety of these agents. The Antihypertensive and Lipid-Lowering treatment to prevent Heart Attack Trial (ALLHAT) was a study of 33,357 patients aged >55 years with hypertension and at least one other common heart disease risk factor. The patients were randomized to one of four antihypertensive regimens: chlorthalidone, a diuretic, an α-blocker, amlodipine, the calcium channel blocker, and lisinopril, an ACE inhibitor.[74] Details of the study design and inclusion and exclusion criteria have been published. A primary outcome of combined fatal CHD and nonfatal myocardial infarction occurred in 2956 participants with no difference between the treatment groups. All-cause mortality also did not differ between the treatment groups.

A second trial entitled The Valsartan Antihypertensive Long-term Use Evaluating (VALUE) trial was designed specifically to test the hypothesis that the angiotensin receptor blocker valsartan would be superior to the dihydropyridine calcium channel blocker amlodipine for the same blood pressure control. The investigators proposed that valsartan would reduce cardiac morbidity and mortality more than amlodipine in hypertensive patients at high risk for a cardiovascular event. A total of 15,245 patients over the age of 50 years participated until 1450 events had accumulated and were followed a mean of 4.2 years.[75]

Blood pressure was reduced by both treatments, however, the amlodipine-based therapies were more effective, particularly early in the study, achieving a 4.0/2.1 mm Hg lower pressure in the amlodipine compared with the valsartan group at 1 month and 1.5/1.3 mm Hg at 1 year. Most importantly, there was no evidence of harm in the patient population but actually a nonstatistically significant slightly lower overall event rate occurred in the amlodipine group: 810 patients in the valsartan group (10.6%, 25.5 per 1000 patient years) and 789 in the amlodipine group (24.7 per 1000 patient years).

In addition, of the secondary outcomes, myocardial infarction was significantly ($P = 0.02$) more frequent in the valsartan group compared with the amlodipine group (Fig. 5–5). It has been hypothesized by the authors that the lower blood pressures in the calcium channel group may explain the lack of superiority of the angiotensin receptor blocker but it seems highly unlikely that it could also explain the statistically significantly

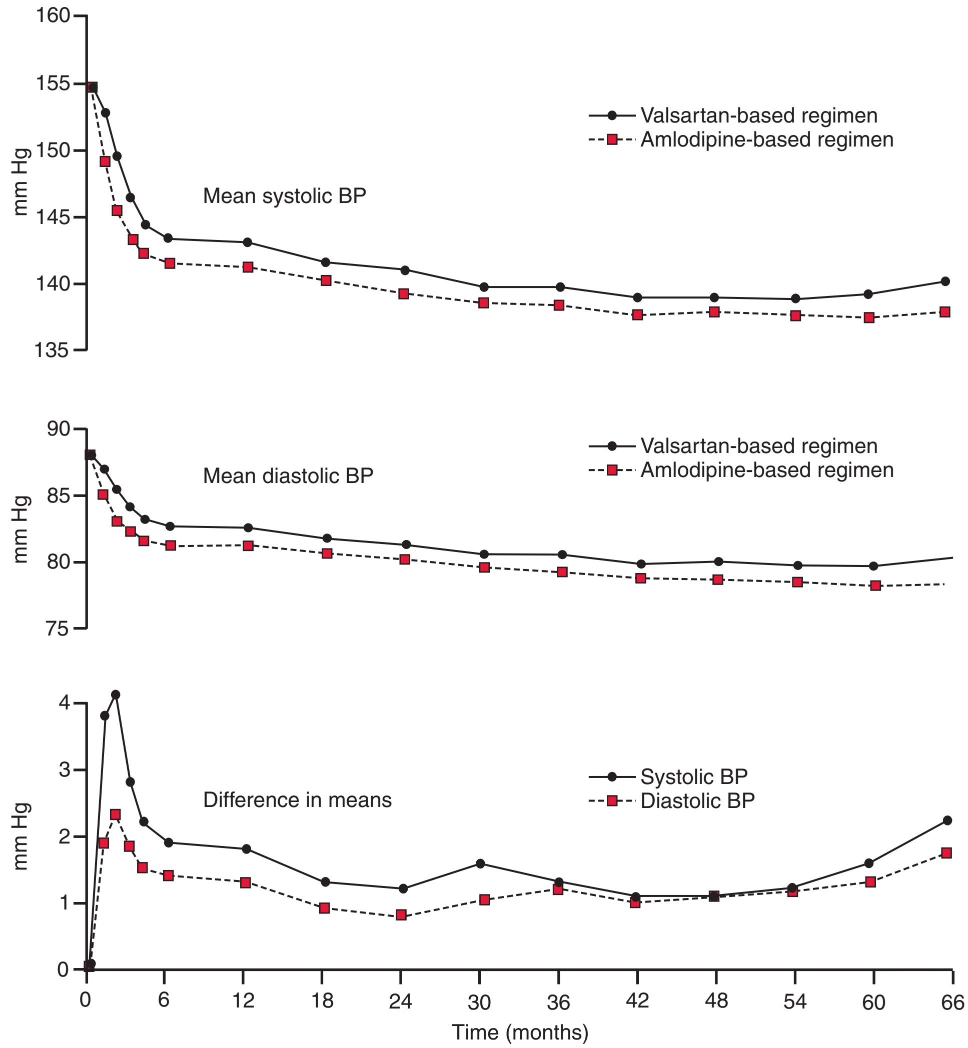

Figure 5–5 **Systolic and diastolic BP and differences (valsartan-amlodipine) in BP between treatment groups during follow-up.** BP difference between the two groups in the VALUE trial was significant (<0.0001) at every time point favoring the amlodipine-based regimen. Overall differences in systolic BP = 2.23 mm Hg (SE 0.18); overall differences in diastolic BP = 1.59 mm Hg (SE 0.11). (Redrawn with permission from Julius S, Kjeldsen V, Weber M, et al., for the VALUE trial group: Outcomes in hypertensive patients at high cardiovascular risk treated with regimens based on valsartan or amlodipine: The VALUE randomised trial. Lancet 2004;363:2024.)

lower infarction rate based on our current understanding of the pathophysiology of acute coronary syndromes. Based on these two completed studies of the ACE inhibitors and angiotensin receptor blockers (ARBs), both in hypertensive patients at high risk for cardiovascular events that were neutral or slightly favorable compared with a diuretic, ACE inhibitors and angiotensin receptor blockers, it is hoped that these unfortunate accusations against a class of cardiovascular agents, when only a few were responsible, finally can be closed.

The issue of choice of antihypertensive agents and risk of new onset diabetes has now also favored calcium channel blockers as neutral agents compared with diuretics and β-blockers. However, ACE inhibitors and angiotensin receptor blockers reverse the insulin resistance in this arena. The efficacy of blood pressure control and the efficacy with dihydropyridines such as amlodipine indicate that it is likely these agents will play an important role in combination with renin-angiotensin-aldosterone system (RAAS) inhibitors because of their efficacy in blood pressure lowering and their demonstrated safety.

β-ADRENERGIC BLOCKERS

β-Blockers, which constitute a major pharmacotherapeutic advance, were conceived initially for the treatment of patients with angina pectoris and arrhythmias; however, they also have therapeutic effects in many other clinical disorders, including systemic hypertension, hypertrophic cardiomyopathy, congestive cardiomyopathy,[76] mitral valve prolapse, silent myocardial ischemia, migraine, glaucoma, essential tremor, and thyrotoxicosis. β-Blockers have been effective in treating unstable angina and reducing the risks of cardiovascular death and nonfatal reinfarction in patients who have survived an acute MI.[77] β-Adrenergic receptor blockade is also a potential treatment modality, with and without fibrinolytic therapy, to reduce the extent of myocardial injury and death during the hyperacute phase of MI.

β-Adrenergic Receptors

The effects of an endogenous hormone or exogenous drug depend ultimately on physiochemical interactions with macromolecular structures of cells called *receptors*. *Agonists* interact with a receptor and elicit a response; *antagonists* interact with receptors and prevent the action of agonists.

In the case of catecholamine action, the circulating hormone or drug ("first messenger") interacts with its specific receptor on the external surface of the target cells. The drug hormone/receptor complex, mediated by the G protein G_s, activates the enzyme adenyl cyclase on the internal surface of the plasma membrane of the target cell, which accelerates the intracellular formation of cAMP. cAMP-dependent protein kinase ("second messenger") then stimulates or inhibits various metabolic or physiological processes.[78-80] Catecholamine-induced increases in intracellular cAMP are usually associated with the stimulation of β-adrenergic receptors, whereas α-adrenergic receptor stimulation is mediated by G protein G_i and is associated with lower concentrations of cAMP, and possibly increased amounts of GMP in the cell. These different receptor effects may result in the production of opposing physiological actions from catecholamines, depending on which adrenergic receptor system is activated.

Most research on receptor action previously bypassed the initial binding step and the intermediate steps and examined either the accumulation of cAMP or the end step, the physiological effect. Radioactive agonists or antagonists (radioligands) that attach to and label the receptors have been used to study binding and hormone action.[79-81] The cloning of adrenergic receptors has also revealed important clues about receptor function.[79]

In contrast to the older concept of adrenergic receptors as static entities in cells, which simply serve to initiate the chain of events, newer theories hold that the adrenergic receptors are subject to a wide variety of controlling influences that result in dynamic regulation of adrenergic receptor sites or their sensitivity to catecholamines, or both.[82] Changes in tissue concentration of receptor sites are probably involved in mediating important fluctuations in tissue sensitivity to drug action.[80,81,83] These principles may have significant clinical and therapeutic implications. For example, an apparent increase in the number of β-adrenergic receptors, and thus a supersensitivity to agonists, may be induced by chronic exposure to antagonists.[80,83] With prolonged adrenergic receptor blocker therapy, receptor occupancy by catecholamines can be diminished and the number of available receptors can be increased.[83] When the β-adrenergic receptor blocker is withdrawn suddenly, an increased pool of sensitive receptors is available for endogenous catecholamine stimulation. The resultant adrenergic stimulation may precipitate unstable angina pectoris, an MI, or both.[84] Specific gene polymorphisms of both the β_1 and β_2 receptors may also influence the pharmacologic response to β-blocking agents.[85]

Effects in Angina Pectoris

Ahlquist[86] demonstrated that sympathetic innervation of the heart causes the release of norepinephrine, activating β-adrenergic receptors in myocardial cells. This adrenergic stimulation causes an increment in heart rate, isometric contractile force, and maximal velocity of muscle fiber shortening, all of which lead to an increase in cardiac work and myocardial oxygen consumption.[87] The decrease in intraventricular pressure and volume caused by the sympathetic mediated enhancement of cardiac contractility tends to reduce myocardial oxygen consumption by reducing myocardial wall tension (LaPlace law).[88] Although there is a net increase in myocardial oxygen demand, this is normally balanced by an increase in coronary blood flow. Angina pectoris is believed to occur when oxygen demand exceeds supply (i.e., when coronary blood flow is restricted by coronary atherosclerosis).[58,89] Because the conditions that precipitate anginal attacks (e.g., exercise, emotional stress, food) cause an increase in cardiac sympathetic activity, it might be expected that blockade of cardiac β-adrenergic receptors would relieve anginal symptoms. It is on this basis that the early clinical studies with β-blocking drugs in patients with angina pectoris were initiated.[90]

Three main factors—heart rate, ventricular systolic pressure, and the size of the left ventricle-contribute to the myocardial oxygen requirements of the left ventricle. Of these, heart rate and systolic pressure appear to be important (the product of heart rate multiplied by the systolic blood pressure is a reliable index for predicting the precipitation of angina in a given patient).[91,92] However, myocardial contractility may be even more important.[93]

The reduction in heart rate effected by β-blockade has two favorable consequences: (l) a decrease in blood pressure, thus reducing myocardial oxygen needs; and (2) a longer diastolic filling time associated with a slower heart rate, allowing for increased coronary perfusion.[93] β-blockade also reduces exercise-induced blood pressure increments, the velocity of cardiac contraction, and oxygen consumption at any patient's workload (Table 5–5).[91,92] After treatment, a reduced heart rate variability, a marker for abnormal autonomic control of the heart, or low exercise tolerance may predict those patients who will respond best to treatment with β-blockade.[93-95] Despite the favorable effects on heart rate, the blunting of myocardial contractility with β-blockers may be the primary mechanism of their antianginal benefit.[93,96] In normal human coronary arteries, β_2-adrenergic receptor-mediated vasodilatation enhances coronary perfusion, an effect that is impaired by severe atherosclerosis.[97]

Studies in dogs have shown that propranolol causes a decrease in coronary blood flow.[98] However, subsequent experimental animal studies have demonstrated that β-blocker-induced shunting occurs in the coronary circulation, maintaining blood flow to ischemic areas, especially in the subendocardial region.[99] In humans, concomitant with the decrease in myocardial oxygen consumption, β-blockers can cause a reduction in coronary blood flow and an increase in coronary vascular resistance.[100] On the basis of coronary autoregulation, the overall reduction in myocardial oxygen needs with β-blockers may be sufficient cause for this clinically tolerated decrease in coronary blood flow.[92]

Virtually all β-blockers, regardless of whether they have partial agonist activity, α-adrenergic receptor-blocking effects, membrane-stabilizing activity, or general or selective β-blocking properties, produce some degree of increased work capacity without pain in patients with angina pectoris. Therefore, it must be concluded that this results from their common property: blockade of cardiac β-adrenergic receptors (Table 5–6). Both D- and L-propranolol have membrane-stabilizing activity, but only L-propranolol has significant β-blocking activity. The racemic mixture (D,L-propranolol) causes decreases in both heart rate and force of contraction in dogs, whereas the D-isomer has hardly any β-adrenergic receptor-blocking effect. In humans, D-propranolol, which has "membrane" activity but no β-blocking properties, has been found to be ineffective in relieving angina pectoris even at very high doses.[101]

Although exercise tolerance improves with β-blockade, the increments in heart rate and blood pressure with exercise are blunted, and the rate-pressure product (systolic blood pressure multiplied by heart rate) achieved when pain occurs is lower than that reached during a control run.[102] The depressed pressure-rate product at the onset of pain (about 20% reduction from control) is reported to occur with various β-blockers, probably related to decreased cardiac output and possibly a decrease in coronary perfusion. Thus, although there is increased exercise tolerance with β-blockade, patients exercise less than might be expected. This may also relate to the action of β-blockers in increasing LV size, causing increased LV wall tension and an increase in oxygen consumption at a given blood pressure.

Table 5–5 Possible Mechanisms by Which β-Adrenergic-Blocking Agents Protect the Ischemic Myocardium

- Reduction in myocardial consumption, heart rate, blood pressure, and myocardial contractility
- Augmentation of coronary blood flow, increase in diastolic perfusion time by reducing heart rate, augmentation of collateral blood flow, and redistribution of blood flow to ischemic areas
- Prevention of and/or attenuation of atherosclerotic plaque rupture and subsequent coronary thrombosis
- Alterations in myocardial substrate utilization
- Decrease in microvascular damage
- Stabilization of cell and lysosomal membranes
- Shift of oxyhemoglobin dissociation curve to the right
- Inhibition of platelet aggregation
- Inhibition of myocardial apoptosis, allowing natural cell regeneration to occur

Comparison with Other Antianginal Therapies

In a meta-analysis of clinical trial experience over 20 years that compared β-blockers, CCBs, and nitrates in patients who had stable angina pectoris, it was demonstrated that β-blockers provide an equivalent reduction in angina and lead to similar or reduced rates of adverse experiences compared with either CCBs or long-acting nitrates.[53,68,103,104] The rates of cardiac death and MI were not significantly different for β-blockers than for CCBs.

Angina at Rest and Vasospastic Angina

Angina pectoris can be caused by multiple mechanisms, including coronary vasospasm, myocardial bridging, and thrombosis, which appear to be responsible for ischemia in a significant proportion of patients with unstable angina and angina at rest.[68,91-106] Therefore, because β-blockers primarily reduce myocardial oxygen consumption but fail to exert vasodilating effects on coronary vasculature, they may not be totally effective in patients in whom angina is caused or increased by dynamic alterations in coronary luminal diameter.[91] Despite potential dangers in rest and vasospastic angina, β-blockers have been used successfully as monotherapy and in combination with vasodilating antianginal agents in the majority of patients. In addition, there is now evidence that β-blockers can reduce C-reactive protein levels, an inflammatory marker of increased cardiovascular morbidity and mortality.[107]

Combined Use of β-Blockers with Other Antianginal Therapies in Angina Pectoris

Nitrates. As noted earlier, combined therapy with nitrates and β-blockers may be more efficacious for the treatment of angina pectoris than the use of either drug alone.[58,91,105] The primary effects of β-blockers are to cause a reduction in both resting heart rate and the response of heart rate to exercise. Because nitrates produce a reflex increase in heart rate and contractility due to a reduction in arterial pressure, concomitant β-blocker therapy is extremely effective because it blocks this reflex increment in the heart rate. Similarly, the preservation of diastolic coronary blood flow with a reduced heart rate will also be beneficial.[91] In patients with a propensity for myocardial failure who may have a slight increase in heart size

Table 5–6 Pharmacodynamic Properties and Cardiac Effects of β-Adrenergic-Blocking Drugs

with the β-blockers, the nitrates will counteract this tendency by reducing heart size as a result of its peripheral venodilator effects. During the administration of nitrates, the reflex increase in contractility that is mediated through the sympathetic nervous system will be blunted by the presence of β-blockers. Similarly, the increase in coronary resistance associated with β-blocker administration can be ameliorated by the administration of nitrates.[91]

Calcium Channel Blockers. Some CCBs (diltiazem, verapamil) also slow the heart rate and inhibit AV nodal conduction. Combined therapy with β-blockers and CCBs can provide clinical benefits for patients with angina pectoris who remain symptomatic with the use of either agent alone.[108-111] Because adverse cardiovascular effects can also occur with combination treatment, such as heart block and excessive myocardial depression, patients being considered for such treatment must be carefully selected and observed.[108,109]

Hemodynamically, these two types of agents have different effects on the circulation (see Tables 5–3 and 5–6), leading to the possibility of therapeutic combination. Of the combinations, β-blockade plus a DHP, such as nifedipine, is likely to be simplest. The DHPs do not inhibit the SA or AV node and, therefore, can be more readily combined with a β-blocker than can the non-DHPs, such as verapamil and diltiazem. Because the tendency to produce tachycardia with the DHPs is antagonized by the β-blocker, there are no additive effects on the SA or AV node, and through vasodilatation, including coronary vasodilatation, the DHPs can contribute to the antianginal effect. β-Blockade should be combined with the non-DHPs such as verapamil and diltiazem only after consideration of the risks and plans are in place for patient monitoring. With non-DHP CCBs, there is the risk of extreme bradycardia, AV nodal block, or a marked negative inotropic effect. Second-generation CCBs, such as the DHPs amlodipine, felodipine, isradipine, and nicardipine, can also be readily combined with β-blockade.

Ranolazine. The FDA has approved extended-release ranolazine for the treatment of chronic angina in patients who have not achieved an adequate response with other antianginal drugs. Ranolazine's antianginal and anti-ischemic mechanism of action is not known. It should be used in combination with a β-blocker and/or a nitrate (see Appendix 1).[111a,b]

Conditions Associated with Angina Pectoris

Arrhythmias. β-Blockers are an important treatment modality for various cardiac arrhythmias, especially in patients with ischemic heart disease. Although it was initially believed that β-blockers were more effective in treating supraventricular arrhythmias than ventricular arrhythmias, subsequent studies suggest that this may not be the case.[112,113] β-Blockers can be quite useful in the prevention and treatment of ventricular tachyarrhythmias in the setting of myocardial ischemia, mitral valve prolapse, the hereditary QT interval prolongation syndrome, and other cardiovascular conditions, such as cardiomyopathy.[112-122] β-Blockers can be combined with amiodarone with relative safety and synergy of antiarrhythmic action,[123] as well as with implantable cardioverter-defibrillators to reduce the frequency of shocks.[124]

Hypertension. The mechanism of the antihypertensive effect of β-blockade is still under dispute.[125,126] Its effect on overall cardiovascular mortality appears to be similar to other classes of antihypertensive drugs.[127] Initially, β-blockers decrease the heart rate, and cardiac output falls by about 20%, yet the blood pressure does not fall because the arteriolar resistance reflexively increases. Within 24 hours of the start of β-blocker treatment, the peripheral resistance starts to fall, so arterial pressure declines. The mechanism of this delayed hypotensive effect is unclear, but it is thought to involve inhibition of prejunctional β-adrenergic receptors.[128] Alternatively, inhibition of the renin-angiotensin system may account for the delayed vasodilatation.[129] Additional antihypertensive mechanisms may involve a central action and decreased renin release.

Survivors of Acute Myocardial Infarction. β-Blockers have beneficial effects on many determinants of myocardial ischemia (see Table 5–5 and Chapter 11).[77,92,130] The results of placebo-controlled, long-term treatment trials with some β-blockers in survivors of acute MI demonstrated a favorable effect on total mortality rates; cardiovascular mortality rates, including sudden and nonsudden cardiac deaths; and the incidence of nonfatal reinfarction. Patients in these studies included those who had relative contraindications to β-blockade but still appeared to benefit[131] and diabetic patients who also responded favorably to treatment.[132] The beneficial results of β-blocker therapy can be explained by both the antiarrhythmic and the anti-ischemic effects of these drugs.[92,116,133-136] It has also been proposed that β-blockers reduce the risk of atherosclerotic plaque fissure and subsequent thrombosis.[137] Two nonselective β-blockers, propranolol and timolol, are approved for use in reducing the risk of death in MI survivors when started 5 to 28 days after an MI. Metoprolol and atenolol, two β_1-selective blockers, are approved for the same indication, and both can be used intravenously in the hyperacute phase of an MI. β-Blockers have also been suggested as a treatment to reduce the extent of myocardial injury[138-140] and deaths during the hyperacute phase of MI.[141-144] The α/β-blocker carvedilol is indicated to reduce cardiovascular mortality in clinically stable patients who have survived the acute phase of myocardial infarction and have a left ventricular ejection fraction of <40% (with or without symptomatic heart failure).[145] Intravenous and oral atenolol have been shown to be effective in causing a modest reduction in early mortality rates when administered during the hyperacute phase of acute MI.[141] Atenolol and metoprolol reduce early infarct mortality rates by 15%,[141,142] an effect that may be improved on when β-blockade is combined with thrombolytic therapy.[146] Despite all of the evidence showing that β-blockers are beneficial in patients who survive MI,[147-150] they are still considerably underused in clinical practice.[151-155]

"Silent" Myocardial Ischemia. Investigators have observed that not all myocardial ischemic episodes detected on electrocardiography are associated with detectable symptoms.[156] Positron emission imaging techniques validated the theory that these silent ischemic episodes are indicative of true myocardial ischemia.[157] Compared with symptomatic ischemia, the prognostic importance of silent myocardial ischemia that occurs at rest or during exercise has not been determined. β-Blockers are as successful in reducing the frequency and timing of silent ischemic episodes detected by ambulatory electrocardiographic monitoring as they are in reducing the frequency of painful ischemic events.[157-161]

Other Cardiovascular Conditions Associated with Angina Pectoris

Although β-blockers have been studied extensively in patients with angina pectoris, arrhythmias, and hypertension, they

have also been shown to be safe for other cardiovascular conditions associated with angina pectoris.

Hypertrophic Cardiomyopathy. β-Blockers without partial agonist activity have been proved to be effective for patients with hypertrophic cardiomyopathy.[162,163] These drugs are useful for reducing dyspnea, angina, and syncope.[130,164] β-Blockers have also been shown to lower the intraventricular pressure gradient both at rest and with exercise.

The outflow pressure gradient is not the only abnormality in hypertrophic cardiomyopathy; more important is the loss of ventricular compliance, which impedes normal LV function. It has been shown through both invasive and noninvasive methods that propranolol can improve LV function in this condition.[165] The drug also produces favorable changes in ventricular compliance while it relieves symptoms. Propranolol has been approved for this condition and may be combined with the CCB verapamil or disopyramide in patients who do not respond to the β-blocker alone.

The salutary hemodynamic and symptomatic effects produced by β-blockers derive from their inhibition of sympathetic stimulation of the heart.[166] There is no evidence that the drug alters the primary cardiomyopathic process; many patients remain in or return to their severely symptomatic state, and some patients die despite their administration.[162,163]

Congestive Cardiomyopathy. The ability of intravenous sympathomimetic amines to effect an acute increase in myocardial contractility through stimulation of the β-adrenergic receptor had prompted the hope that the use of oral catecholamine analogs could provide long-term benefit for patients with severe heart failure. However, observations concerning the regulation of the myocardial adrenergic receptor and abnormalities of β-adrenergic receptor-mediated stimulation of the failing myocardium have caused a critical reappraisal of the scientific validity of sustained β-adrenergic receptor stimulation.[146,167-169] Evidence suggests that β-adrenergic receptor blockade may, when tolerated, have a favorable effect on the underlying cardiomyopathic process.[170]

Enhanced sympathetic activation is seen consistently in patients with congestive heart failure and is associated with decreased exercise tolerance,[171] hemodynamic abnormalities,[172] and increased mortality rates.[173] Increases in sympathetic tone can potentiate the renin-angiotensin system in patients, leading to increased salt and water retention, arterial and venous constriction, and increments in ventricular preload and afterload.[170] Elevated levels of catecholamines can increase heart rate and cause coronary vasoconstriction.[92] They can adversely influence myocardial contractility on the cellular level,[174,175] while causing myocyte hypertrophy[175,176] and vascular remodeling. Catecholamines can stimulate growth and provoke oxidative stress in terminally differentiated cardiac cells; these two factors can trigger the process of programmed cell death known as *apoptosis*.[177,178] Finally, they can increase the risk of sudden death in patients with congestive heart failure by adversely influencing the electrophysiologic properties of the failing heart.[179]

Controlled trials with several different β-blockers in patients with either ischemic or nonischemic cardiomyopathy showed that these drugs improve symptoms, ventricular function, and functional capacity, while reducing the need for hospitalization.[76,180,181] A series of placebo-controlled clinical trials with the α-β-blocker carvedilol[182] and the β_1-selective agents bisoprolol and metoprolol[183-185] have shown a mortality benefit in patients with New York Heart Association functional class II to IV heart failure when the drug was used in addition to diuretics, ACE inhibitors, and digoxin. For patients with class II to III heart failure, initial treatment with a β-blocker followed by an ACE inhibitor was found to be at least as effective as beginning with an ACE inhibitor.[186]

The mechanisms of benefit with β-blocker use are not yet known. Possible mechanisms for β-blocker benefit in chronic heart failure include the upregulation of impaired β-adrenergic receptor expression in the heart[146,187,188] and an improvement in impaired baroreceptor functioning, an effect that can inhibit excess sympathetic outflow.[170] It has been suggested that long-term therapy with β-blockers improves the left atrial contribution to LV filling[189] while increasing the levels of cardiac natriuretic peptides.[190,191]

Mitral Valve Prolapse. Atypical chest pain, malignant arrhythmias, and nonspecific ST- and T-wave abnormalities have been observed with this condition. By decreasing sympathetic tone, β-blockers have been shown to be useful for relieving the chest pains and palpitations that many of these patients experience and for reducing the incidence of life-threatening arrhythmias and other electrocardiographic abnormalities.[192]

Dissecting Aneurysms. β-Blockade plays a major role in the treatment of patients with acute aortic dissection. During the hyperacute phase, β-blockers reduce the force and velocity of myocardial contraction (dP/dT) and, hence, the progression of the dissecting hematoma.[193] Moreover, β-blockade should be initiated simultaneously with the institution of other antihypertensive therapy (e.g., SNP) that may cause reflex tachycardia and increases in cardiac output, factors that can aggravate the dissection process. β-Blockade is administered intravenously to reduce the heart rate to below 60 beats/min. Once a patient is stabilized (i.e., adequate control of heart rate and blood pressure and no further pain from dissection) and long-term medical management is contemplated, the patient should be maintained on oral β-blocker therapy to prevent the recurrence of dissection.[193]

Syndrome X. A dysfunction of small coronary arterial vessels has been hypothesized to be responsible for syndrome X, a chest pain syndrome often presenting without evidence of large-vessel coronary artery disease. The treatment of syndrome X, however, remains largely empiric and often unsatisfactory. Some investigators found that β-blockers rather than CCBs and nitrates were useful in relieving symptoms,[194] suggesting that they may be the preferred drugs when starting pharmacologic treatment for this condition.

Perioperative Therapy in High-Risk Patients with Ischemic Heart Disease. Cardiovascular complications are the most important causes of perioperative complications and death in high-risk patients undergoing major vascular and nonvascular surgical procedures. β-Blocker treatment before surgery reduces the perioperative incidence of death from cardiac causes and nonfatal MI.[131,195-197]

Pharmacologic Differences Among β-Adrenergic Receptor-Blocking Drugs

More than 100 β-blockers have been synthesized, and more than 30 are available worldwide for clinical use.[91] Selectivity for two subgroups of the β-adrenergic receptor population has been prominent in the development of β-blockers: β_1-adrenergic receptors in the heart and β_2-adrenergic receptors in the peripheral circulation and bronchi.[91,198] More

controversial has been the introduction of β-blockers with α-adrenergic receptor-blocking actions, varying amounts of selective and nonselective intrinsic sympathomimetic activity (partial agonist activity), CCB activity, nitric oxide potentiating action, and nonspecific membrane-stabilizing effects (Table 5–7).[164] There also are pharmacokinetic differences among β-blockers that may be of clinical importance.[198]

Fifteen β-blockers are marketed in the United States for cardiovascular disorders: *propranolol* for angina pectoris, arrhythmias, systemic hypertension, migraine prophylaxis, essential tremor, and hypertrophic cardiomyopathy and to reduce the risk of cardiovascular death in survivors of an acute MI; *nadolol* for hypertension and angina pectoris; *timolol* for hypertension and to reduce the risk of cardiovascular death and nonfatal reinfarction in survivors of MI and in a topical form for glaucoma; *atenolol* and *metoprolol* for hypertension and angina and in intravenous and oral formulations to reduce the risk of cardiovascular death in survivors of MI; *penbutolol*, *bisoprolol*, *pindolol*, and *carvedilol* for hypertension; *betaxolol* and *carteolol* for hypertension and in a topical form for glaucoma; *acebutolol* for hypertension and ventricular arrhythmias; intravenous *esmolol* for supraventricular arrhythmias; *sotalol* for atrial and ventricular arrhythmias; and *labetalol* for hypertension and in an intravenous form for hypertensive emergencies.[164,198-203] *Carvedilol*, *metoprolol*, and *bisoprolol* are approved for clinical use in the treatment of congestive heart failure. Nebivolol, a β_1-selective agent with nitric oxide potentiating action, is now under review by the FDA for clinical use in hypertension.[204]

Despite the extensive experience with β-blockers in clinical practice, there have been no studies suggesting that any of these agents have major advantages or disadvantages compared with the others for the treatment of many cardiovascular diseases. When any available β-blocker is titrated properly, it can be effective in patients with arrhythmia, hypertension, or angina pectoris (see Table 5–7).[164,198-203] However, one agent may be more effective than other agents in reducing adverse reactions in some patients and in managing specific situations.

Potency

β-Blockers are competitive inhibitors of catecholamine binding at β-adrenergic receptor sites. The dose-response curve of the catecholamine is shifted to the right; that is, a given tissue response requires a higher concentration of agonist in the presence of β-blockers.[130] β_1-Blocking potency can be assessed by the inhibition of tachycardia produced by isoproterenol or exercise (the more reliable method in the intact organism); potency varies among compounds.[130] These differences in potency are of no therapeutic relevance; however, they do explain the different drug doses needed to achieve effective β-blockade when initiating therapy in patients or when switching from one agent to another.[198,205,206]

β_1-Selectivity

β-Blockers may be classified as *selective* or *nonselective* according to their relative abilities to antagonize the actions of sympathomimetic amines in some tissues at lower doses than those required in other tissues.[198,199,205,206] When used in low doses, β_1-selective blockers such as acebutolol, betaxolol, bisoprolol, esmolol, atenolol, and metoprolol inhibit cardiac β_1-adrenergic receptors but have less influence on bronchial and vascular β-adrenergic receptors (β_2). In higher doses, however, β_1-selective blockers also block β_2-adrenergic receptors. Accordingly, β_1-selective agents may be safer than nonselective ones in patients with obstructive pulmonary disease, because β_2-adrenergic receptors remain available to mediate adrenergic bronchodilatation.[207] Even relatively selective β-blockers may aggravate bronchospasm in certain patients, so these drugs should generally not be used in patients with active bronchospastic disease.

A second theoretical advantage is that, unlike nonselective β-blockers, β_1-selective blockers in low doses may not block the β_2-adrenergic receptors that mediate the dilatation of arterioles. During the infusion of epinephrine, nonselective β-blockers can cause a pressor response by blocking β_2-adrenergic receptor-mediated vasodilatation, because β-adrenergic vasoconstrictor receptors are still operative. Selective β_1-blockers may not induce this pressor effect in the presence of epinephrine and may lessen the impairment of peripheral blood flow. It is possible that leaving the β_2-adrenergic receptors unblocked and responsive to epinephrine may be functionally important in some patients with asthma, hypoglycemia, hypertension, or peripheral vascular disease who are treated with β-blockers.[164,198,199]

Intrinsic Sympathomimetic Activity (Partial Agonist Activity)

Certain β-blockers possess intrinsic sympathomimetic activity (partial agonist activity) at β_1-adrenergic receptor sites, β_2-adrenergic receptor sites, or both. In a β-blocker, this property is identified as a slight cardiac stimulation that can be blocked by propranolol.[164,198,202] The β-blockers with this property partially activate the β-adrenergic receptor in addition to preventing the access of natural or synthetic catecholamines to the receptor. Dichloroisoprenaline, the first β-adrenergic receptor-blocking drug to be synthesized, exerted such marked partial agonist activity that it was unsuitable for clinical use. However, compounds with less partial agonist activity are effective β-blockers. The partial agonist effects of β-blockers such as pindolol differ from those of the agonists epinephrine and isoproterenol in that the maximum pharmacologic response that can be obtained is low, although the affinity for the receptor is high. In the treatment of patients with arrhythmias, angina pectoris of effort, and hypertension, drugs with mild-to-moderate partial agonist activity appear to be as efficacious as are β-blockers that lack this property. It is still debated whether the presence of partial agonist activity in a β-blocker constitutes an overall advantage or disadvantage in cardiac therapy.[202] Drugs with partial agonist activity cause less slowing of the heart rate at rest than do propranolol and metoprolol, although the increments in heart rate with exercise are similarly blunted. These β-blockers reduce peripheral vascular resistance and may cause less depression or AV conduction than drugs that lack these properties.[202,208] Some investigators claim that partial agonist activity in a β-blocker protects against myocardial depression, adverse lipid changes, bronchial asthma, and peripheral vascular complications, as caused by propranolol.[202,208-210]

Table 5–7 Properties of Various β-Adrenoceptor Antagonist Agents: Noncardioselective Versus Cardioselective and Vasodilatory Agents

Generic Name (Trade Name)	ISA	Plasma Half-Life	Lipid* Solubility	First-Pass Effect	Loss by Liver/Kidney	Plasma Protein Binding (%)	Usual Dose for Angina (Other Indications)	Usual Doses as Sole Therapy for Mild/Moderate Hypertension
Noncardioselective								
Propranolol†‡ (Inderal)	–	1-6	+++	++	Liver	90	80 mg bid usually adequate (may give 160 mg bid)	Start with 10-40 mg bid.; mean 160-320 mg/day, 1 or 2 doses
(Inderal LA)	–	8-11	+++	++	Liver	90	80-320 mg qd	80-320 mg daily
(Innopran XL)	–	8-11	+++	++	Liver	90	Not indicated	80-120 mg hs (at bedtime)
Carteolol† (Cartrol)	+	5-6	0/+	0	Kidney	20-30	Not evaluated	2.5-10 mg single dose
Nadolol†‡ (Corgard)	–	20-24	0	0	Kidney	30	40-80 mg qd; up to 240 mg	40-80 mg daily; up to 320 mg
Penbutolol† (Levatol)	+	20-25	+++	++	Liver	98	Not studied	10-20 mg daily
Sotalol§ (Betapace; Betapace AF)	–	7-18 (mean 12)	0	0	Kidney	5	80-240 mg bid in two doses for serious ventricular arrhythmias; up to 160 mg bid for atrial fibrillation, flutter	80-320 mg/day; mean 190 mg per day
Timolol† (Blocadren)	–	4-5	+	+	Liver, kidney	60	10 mg bid after MI	10-20 mg bid
Cardioselective								
Acebutolol† (Sectral)	++	8-13	0		Liver, kidney	15	400-1200 mg/day in two doses for PVCs	400-1200 mg/day; can be given as a single dose
Atenolol†‡ (Tenormin)	–	6-7	0	0	Kidney	10	50-200 mg qd	50-100 mg daily
Betaxolol† (Kerlone)	–	14-22	++	++	Liver, kidney	50	–	10-20 mg daily
Bisoprolol† (Zebeta)	–	9-12	+	0	Liver, kidney	30	10 mg qd (not in the U.S.)	2.5-40 mg daily
Metoprolol†‡ (Lopressor)		3-7	+	++	Liver	12	50-200 mg bid	100-400 mg/day in 1 or 2 doses
(Toprol-XL)		(slow release)	+	++	Liver	12	100-400 mg qd	As above, 1 dose

Table 5–7 Properties of Various β-Adrenoceptor Antagonist Agents: Noncardioselective Versus Cardioselective and Vasodilatory Agents—cont'd

Generic Name (Trade Name)	ISA	Plasma Half-Life	Lipid* Solubility	First-Pass Effect	Loss by Liver/Kidney	Plasma Protein Binding (%)	Usual Dose for Angina (Other Indications)	Usual Doses as Sole Therapy for Mild/Moderate Hypertension
Vasodilatory β-Blockers, Noncardioselective								
Labetalol† (Trandate, Normodyne)	–	6-8	+++	++	Liver, some kidney	90	As for hypertension	300-600 mg/day in 3 doses; top dose 2400 mg/day
Pindolol† (Visken)	$\beta_1\beta_2$	4	+	+	Liver, kidney	55	2.5-7.5 mg tid (not in the U.S.)	5-30 mg in two daily doses
Carvedilol†¶ (Coreg)	–	6	+	++	Liver	95	In the U.S., U.K., licensed for heart failure up to 25 mg bid; start with low dose	12.5-25 mg bid
Vasodilatory β-Blockers, Selective								
Nebivolol	–	6-10	++	++	Liver, kidney	98	2.5-10 mg qd	2.5-10 mg qd

*Octanol-water distribution coefficient (pH 7.4, 37°C) where 0 is ≤0.5; + is 0.5-2; ++ is 2-10; and +++ is ≥10.
†Approved by the U.S. Food and Drug Administration for hypertension.
‡Approved by the U.S. Food and Drug Administration for angina pectoris.
§Approved for life-threatening ventricular tachyarrhythmias.
¶Approved for heart failure.
ISA, intrinsic sympathomimetic activity; PVC, premature ventricular contraction.
Modified from Opie LH, Yusuf S: Beta-Blocking Agents. In Opie LH, Gersh BJ (eds): Drugs for the Heart, 5th ed. Philadelphia: WB Saunders, 2001, pp 1-32.

The evidence to support these claims is not conclusive, and more definitive clinical trials will be necessary to resolve these issues.

α-Adrenergic Activity

Labetalol is a β-blocker with antagonistic properties at both α- and β-adrenergic receptors, and it has direct vasodilator activity.[130,164,211] Labetalol has been shown to be 6 to 10 times less potent than phentolamine at α-adrenergic receptors, 1.5 to 4 times less potent than propranolol at β-adrenergic receptors, and is itself 4 to 16 times less potent at α- than at β-adrenergic receptors.[130,164,211] Like other β-blockers, it is useful in the treatment of hypertension and angina pectoris.[130,212,213] Unlike most β-blockers, however, the additional α-adrenergic receptor-blocking actions of labetalol lead to a reduction in peripheral vascular resistance that may maintain cardiac output.[130,211] Whether concomitant α-adrenergic receptor-blocking activity is actually advantageous in a β-blocker remains to be determined.

Carvedilol is another β-blocker with additional β-adrenergic receptor-blocking activity. Carvedilol has an α_1- to β-blockade ratio of 1:10. On a milligram-to-milligram basis, carvedilol is about 2 to 4 times more potent than propranolol as a β-blocker.[76] In addition, carvedilol has antioxidant and antiproliferative activities.[214] Carvedilol has been used for the treatment of hypertension and angina pectoris and is approved as a treatment for hypertension and for patients with symptomatic heart failure.[76,215]

Nitric Oxide Potentiating Effect

A novel aspect of the pharmacology of the β_1-selective antagonist nebivolol is its ability to produce endothelium-dependent vasodilation through a nitric oxide pathway. Nebivolol produces vasodilation by acting as a β_3-receptor agonist, which increases the activity of nitric oxide.[204] Nitric oxide activity is also augmented by nebivolol through the prevention of nitric oxide deactivation.[204] The nitric oxide-mediated vasodilatory effects of nebivolol occur primarily in the small arteries, which contributes to the effect of the drug on arterial blood pressure.[204]

Pharmacokinetics

Although the β-blockers as a group have similar therapeutic effects, their pharmacokinetic properties are markedly different.[164,206,216,217] Their varied aromatic ring structures lead to differences in completeness or gastrointestinal absorption, amount of first-pass hepatic metabolism, lipid solubility, protein binding, extent of distribution in the body, penetration into the brain, concentration in the heart, rate of hepatic biotransformation, pharmacologic activity of metabolites, and renal clearance of a drug and its metabolites, which may influence the clinical usefulness of these drugs in some patients.[164,198,206,216,217] The desirable pharmacokinetic characteristics of β-blockers in general are a lack of major individual differences in bioavailability and in metabolic clearance of the drug and a rate of removal from active tissue sites that is slow enough to allow longer dosing intervals.[164,198]

The β-blockers can be divided by their pharmacokinetic properties into two broad categories: (1) those eliminated via hepatic metabolism, which tend to have relatively short plasma half-lives; and (2) those eliminated unchanged by the kidney, which tend to have longer half-lives.[198] Propranolol and metoprolol are both lipid soluble, are almost completely absorbed by the small intestine, and are largely metabolized by the liver. They tend to have more variable bioavailability and relatively short plasma half-lives.[164,199,206,217] A lack of correlation between the duration of clinical pharmacologic effect and plasma half-life may allow these drugs to be administered once or twice daily.[198]

In contrast, agents such as atenolol and nadolol are more water soluble, are incompletely absorbed through the gut, and are eliminated unchanged by the kidney.[200,201] They tend to have less variable bioavailability in patients with normal renal function, in addition to longer half-lives, allowing once-a-day dosing.[200,201] The longer half-lives may be useful in patients who find compliance with frequent β-blocker dosing to be a problem.[200]

Long-acting sustained-release preparations of propranolol and metoprolol are available. Studies have shown that long-acting propranolol and metoprolol can provide a much smoother curve of daily plasma levels than can comparable divided doses of conventional immediate-release formulations.[218-220] In addition, a delayed-release sustained-release formulation of propranolol is available that is designed to target early morning elevations in blood pressure and heart rate related to circadian rhythm.[221]

The specific pharmacokinetic properties of individual β-blockers (first-pass metabolism, active metabolites, lipid solubility, and protein binding) may be clinically important.[130] When drugs with extensive first-pass metabolism are taken by mouth, they undergo so much hepatic biotransformation that relatively little drug reaches the systemic circulation.[164,198,206] Depending on the extent of first-pass effect, an oral dose of β-blocker must be larger than an intravenous dose to produce the same clinical effects.[199,206] Some β-blockers are transformed into pharmacologically active compounds (acebutolol) rather than inactive metabolites.[222] The total pharmacologic effect depends on the amount of the drug administered and its active metabolites.[217] Characteristics of lipid solubility in a β-blocker have been associated with the ability of the drug to concentrate in the brain,[164,198] and many side effects of these drugs that have not been clearly related to β-blockade may result from their actions on the central nervous system (e.g., lethargy, mental depression, and hallucinations).[198,201] It is still not certain, however, whether drugs that are less lipid soluble cause fewer of these adverse reactions.[200,201,223,224]

There are genetic polymorphisms that can influence the metabolism of various β-blockers, including propranolol, metoprolol, timolol, and carvedilol.[225,226] A one-codon difference of cytochrome P450 2D6 may explain a significant proportion of interindividual variation in the pharmacokinetics of propranolol in Chinese subjects.[225] There is no effect of exercise on the pharmacokinetics of propranolol.[227]

Adverse Effects of β-Adrenergic Receptor Blockers

An evaluation of adverse effects is complex because of the use of different definitions of side effects, the kinds of patients studied, study design features, and different methods

of ascertaining and reporting adverse side effects among studies.[228-230] Overall, the types and frequencies of adverse effects attributed to various β-blocker compounds appear similar.[228,229] The side effect profiles resemble those seen with concurrent placebo treatments, attesting to the remarkable safety margin of β-blockers.[230]

Adverse effects of β-blockers are an exaggeration of the normal cardiac therapeutic effects resulting in excess bradycardia, AV nodal block, and excess negative inotropic effect. All β-blockers tend to promote bronchospasm, with low doses of β_1-selective agents being the least harmful. Cold extremities occur with both selective and nonselective agents,[231] yet agents with intrinsic sympathomimetic activity may provide a slightly better skin temperature than propranolol, at least during an acute study.[232] The adverse effects of all β-blockers on the peripheral circulation may be less marked than previously thought.[233,234]

Fatigue is a frequent side effect, again found particularly with propranolol, with less of an effect when a β_1-selective or vasodilatory blocker is used, so both central and peripheral hemodynamic mechanisms may be involved.[235] Although one double-blind study shows no difference between the effects of the β_1-selective agent atenolol and placebo,[231] exercise physiologists find that there is some impairment in peak exercise with all β-blockers.

Impotence is often reported by patients who receive β-blockers, who are, however, usually middle-aged men with atherosclerotic arterial disease.[236] In one study, erectile dysfunction occurred in 11% of patients administered a β-blocker for hypertension compared with 26% of these patients administered a diuretic and 3% of placebo-treated patients.[237]

An impaired quality of life found especially with propranolol[238] is theoretically ascribed to its lipid solubility and brain penetration. Yet, a variety of β-blockers other than propranolol and with different pharmacologic properties preserve quality of life in hypertensive patients.[239] Central effects of β-blockers are often subtle and not always explicable by the lipid penetration hypothesis.[240]

β-Blockers have effects on various metabolic parameters, including blood sugar and blood lipids. In a prospective cohort study of 12,550 nondiabetic individuals with hypertension, β-blockers were shown to increase the risk of developing type II diabetes, a finding not observed with thiazide diuretics, ACE inhibitors, or CCBs.[241] This increased risk of diabetes must be weighed against the proven benefits of β-blockers in reducing the risk of cardiovascular events in patients with ischemic heart disease. Studies are needed to determine whether the use of ACE inhibitors in conjunction with β-blockers might counteract the adverse effects of β-blockers with respect to glucose tolerance.[242] Carvedilol has been shown not to affect glycemic control, while improving some components of the metabolic syndrome relative to metoprolol in diabetic patients.[215]

Similarly, β-blockers without intrinsic sympathomimetic activity have been shown in hypertensive patients to decrease high-density lipoprotein cholesterol concentrations by 7% to 10% and raise triglyceride concentrations by 10% to 20%.[209,243,244] These small changes in lipids induced by β-blockers do not appear to diminish the beneficial effects of blood pressure lowering on morbidity and mortality rates from coronary heart disease and stroke.

Contraindications to β-Adrenergic Receptor Blockers

There are several absolute contraindications. Cardiovascular contraindications include severe bradycardia (heart rate of less than 40 beats/min), preexisting high-degree AV nodal block (PR interval of more than 0.24 second without a functioning pacemaker), overt LV failure (except when the β-blocker is administered initially at low doses and under supervision to patients already receiving diuretics, digoxin, and an ACE inhibitor), and active peripheral vascular disease with rest ischemia. Severe bronchospasm is an absolute contraindication, even to β-selective agents. Severe psychological depression is an important relative contraindication, particularly for propranolol.[223]

Overdosage

Suicide attempts and accidental overdosing with β-blockers are being described with increasing frequency. Because β-blockers are competitive pharmacologic antagonists, their life-threatening effects (bradycardia, myocardial and ventilatory failure) can be overcome with an immediate infusion of a β-agonist agent, such as isoproterenol or dobutamine.[245] In situations where catecholamines are not effective, intravenous glucagon, amrinone, or milrinone has been used.[245] There are no published recommended doses of intravenous catecholamines or phosphodiesterase inhibitors to treat β-blocker overdose. These agents should be used in their usual pharmacologic concentration until one is certain that reversal of β-blocker toxicity (reversal of heart blocks, excessive bradycardia, and myocardial depression) has occurred.

Monitoring of cardiorespiratory function is necessary for at least 24 hours in an intensive care unit after the patient responds to treatment of the β-blocker overdose. Patients who recover usually have no long-term sequelae; however, they should be observed for the cardiac signs of sudden β-blocker withdrawal.[245]

β-Adrenergic Receptor Blocker Withdrawal

After abrupt cessation of chronic β-blocker therapy, exacerbation of angina pectoris and, in some cases, acute MI and death have been reported.[84,246,247] Observations made in multiple double-blind randomized trials have confirmed the reality of a *propranolol withdrawal reaction*.[84,248] The mechanism for this reaction is unclear. There is some evidence that the withdrawal phenomenon may be due to the generation of additional β-adrenergic receptors during the period of β-blockade. When the β-blocker is then withdrawn, the increased β-adrenergic receptor population readily results in excessive β-adrenergic receptor stimulation, which is clinically important when the delivery and use of oxygen are finely balanced, as occurs in ischemic heart disease. Other suggested mechanisms for the withdrawal reaction include heightened platelet aggregability, an elevation in thyroid hormone activity, and an increase in circulating catecholamines.[84]

Similar withdrawal problems have been seen with β-blocker discontinuation in patients with heart failure previously responsive to treatment.[249,250]

Drug-Drug Interactions

β-Blockers are commonly used with other cardiovascular and noncardiovascular drugs, and the list of drugs with which they interact is extensive (Table 5–8).[229] The majority of the reported interactions have been associated with propranolol, the best studied β-blocker, and may not necessarily apply to other drugs in this class.

THROMBOSIS AND ISCHEMIC CARDIOVASCULAR DISEASE

The hemostatic process is a delicate balance of pro- and antithrombotic factors in the vasculature. Normal hemostasis prevents uncontrolled hemorrhage, however, these same

Table 5–8 Drug Interactions of β-Adrenergic-Blocking Agents

Cardiac Drugs	Interacting Drugs	Mechanism	Consequence	Prophylaxis
Hemodynamic Interactions				
All β-blockers	Calcium antagonists, especially nifedipine.	Added hypotension	Risk of myocardial ischemia	BP control, adjust doses
	Verapamil or diltiazem	Added negative inotropic effect	Risk of myocardial failure	Check for CHF, adjust doses
	Flecainide	Hypotension	Check LV function, flecainide levels	
	Sympathomimetics (S)	Opposing effects	Loss of clinical benefit	Avoid S
Electrophysiologic Interactions				
All β-blockers	Verapamil	Added inhibition of SA and AV nodes	Bradycardia, asystole, complete heart block	Exclude "sick sinus" syndrome, AV nodal disease; adjust dose; exclude prodrug LV failure
	Diltiazem	Added negative inotropic effect	Excess hypotension	
Hepatic Interaction				
Propranolol (P)	Cimetidine (C)	C decreases P metabolism	Excess P effects	Reduce both drug doses
	Lidocaine (L)	Low hepatic blood flow	Excess L effects	Reduce L dose
Metoprolol (M)	Verapamil (V)	V decreases M metabolism	Excess M effects	Reduce M dose
	Cimetidine (C)	C decreases M metabolism	Excess M effects	Reduce both drug doses
Labetalol (L)	Cimetidine (C)	C decreases L metabolism	Excess L and C effects	Reduce both drug doses
Carvedilol (CV)	Cimetidine (C)	C decreases CV metabolism	Excess CV effects	Reduce both drug doses
Antihypertensive Interactions				
All β-blockers	Indomethacin (I), other NSAIDs	I inhibits vasodilatory prostaglandins	Decreased antihypertensive effect	Omit I; use alternative drugs
Immune-Interacting Drugs				
Acebutolol	Other drugs altering immune status; procainamide, hydralazine, captopril	Theoretical risk of additive immune effects	Theoretical risk of lupus or neutropenia	Check antinuclear factors and neutrophils; low doses during cotherapy

AV, atrioventricular; BP, blood pressure; LV, left ventricular; NSAIDs, nonsteroidal anti-inflammatory drugs; SA, sinoatrial.

pathways regulating hemostasis lead to pathological thrombosis and vessel occlusion. Distinct from venous thrombosis, arterial thrombosis is typically highly dependent on the platelet and vessel wall.[251] In the coronary artery, rupture of atheromatous plaque in variably stenosed vessels and subsequent thrombus formation underlies the majority of acute coronary syndromes. Vessel injury caused by plaque rupture exposes collagen and von Willebrand factor to platelets which adhere and further stimulate thrombus formation. Advances in understanding the mechanisms governing thrombosis have led to the development of new classes and combinations of antithrombotic drugs. Initially, characterization of arachidonic acid metabolism in platelets furthered an understanding of the therapeutic utility of cyclooxygenase inhibitors in vascular disease, most notably aspirin. The discovery and characterization of platelet receptors, such as the adenosine diphosphate (ADP) receptor and the glycoprotein IIb/IIIa complex (GP IIb/IIIa), have been associated with the development of novel classes of antiplatelet drugs, including thienopyridine derivatives and GP IIb/IIIa receptor antagonists.[251] Development of additional classes of antithrombin agents has also contributed to the ongoing changes in the guidelines for antithrombotic agents and the management of ischemic heart disease (Fig. 5–6; Table 5–9).

Platelet Inhibitors

Aspirin

Mechanisms of Action

Aspirin's primary antithrombotic effect is by inhibiting platelet aggregation via inactivation of cyclooxygenase (COX), a key enzyme in platelet arachidonate metabolism. More specifically, aspirin inhibits the cyclooxygenase (COX) activity of prostaglandin (PG) H-synthase, which in turn, blocks the metabolism of arachidonic acid to prostaglandin H_2 (PGH_2), the precursor of thromboxane (TXA_2) and other cyclic prostanoids (prostacyclin and other prostaglandins). In platelets, TXA_2 is synthesized and released in response to a variety of stimuli (i.e., collagen, adenosine diphosphate [ADP], thrombin, platelet activating factor) and acts to amplify the activation signal, promote irreversible platelet

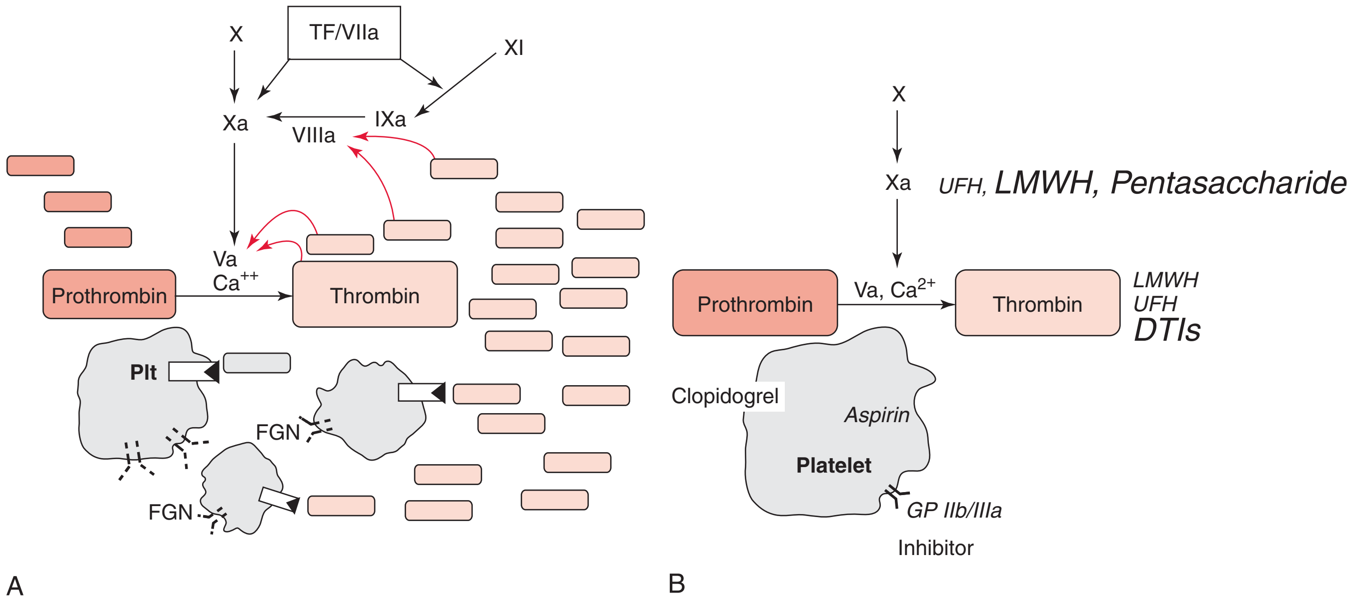

Figure 5–6 **Activated coagulation cascade and platelet aggregation in patients with an acute coronary syndrome. A,** With disruption of a vulnerable plaque, tissue factor (TF) is exposed and ultimately complexes with activated factor VII (VIIa). The TF:VIIa complex converts factor X to its active form (Xa) and triggers the coagulation cascade. Through a multiplier effect, a single molecule of factor Xa leads to downstream production of many molecules of thrombin through its participation in prothrombinase complex along with factor V and calcium (Ca^{++}) on a phospholipid surface, such as membrane of activated platelets (Plt). Following the initial triggering of the coagulation cascade, the process of thrombus formation is perpetuated by factors XI and IXa (intrinsic system). Thrombin amplifies the generation of factors VIIIa and Va that also perpetuates thrombus formation. Thrombin is a potent agonist for platelet activation via binding to thrombin receptor on platelets producing networking between the coagulation cascade and platelet activation. Aggregates of platelets are formed by cross-bridging via attachments of ligands such as fibrinogen (FGN) to the GP IIb/IIIa receptors on adjacent platelets. **B,** Sites of action of antithrombin and antiplatelet agents. Relative strength of actions at various positions is shown semiquantitatively by size of font in diagram. Thus, UFH has similar inhibitory action against thrombin and factor Xa; whereas LMWH has greater relative inhibitory capacity against factor Xa than thrombin. Direct thrombin inhibitors (DTIs) have little effect on generation of thrombin but are potent inhibitors of thrombin that has been formed. In contrast, the pentasaccharide acts more proximally in the coagulation cascade to inhibit formation of factor Xa and limit downstream production of thrombin. Combinations of antithrombins shown and antiplatelet agents (*bottom of diagram*) are effective in reducing the propensity to thrombus formation at the site of a disrupted vulnerable plaque. (Modified from: Antman EM: The search for replacements for unfractionated heparin. Circulation 2001;103:2311.)

aggregation, and cause vasoconstriction. Cyclooxygenase activity is inhibited by aspirin via the acetylation of a single serine residue at position 529 (Ser^{529}) within platelet PGH-synthase. There are two COX isoforms but COX-1 is primarily expressed in mature platelets.[252] Because platelets have minimal capacity for protein synthesis, the inactivation of COX-1 by aspirin is irreversible for the life of the platelet (8 to 10 days). The second COX isoform (COX-2) is inducible in newly formed platelets (8% to 10% of circulating platelets), and prostaglandin E_2 is the main product of platelet or endothelial COX-2 activity.[252] The concentration of newly formed platelets is large enough during periods of increased platelet turnover to produce detectable amounts of COX-2 derived TXA_2.

Aspirin may also influence hemostasis and cardiovascular disease by mechanisms independent of prostaglandin production. Although less clearly defined, the non–prostaglandin-mediated effects of aspirin on hemostasis are thought to be dose dependent and unrelated to COX-1 activity. These effects include vitamin K antagonism, decreased platelet production of thrombin, and acetylation of one or more clotting factors.[253] In addition to its direct platelet effects, aspirin may alter the pathogenesis of cardiovascular disease by protecting low density lipoprotein (LDL) from oxidative modification, improving endothelial dysfunction in atherosclerotic patients, and by attenuating the inflammatory response by acting as an antioxidant.[254]

Indication

Aspirin is an effective antiplatelet agent with proven benefit in the prevention of atherothrombotic complications of cardiovascular disease. Clinical trials have demonstrated that aspirin is effective for both the primary and secondary prevention of myocardial infarction, stroke, and cardiovascular death[255,256] and in the acute management of myocardial infarction, unstable angina, and embolic stroke (see Chapter 1).[256-258] A large, primary-prevention trial among women showed that aspirin lowered the risk of stroke without affecting the risk of myocardial infarction or death from cardiovascular causes.[259] The results from this long-term trial also suggest that alternate day use of low-dose aspirin (100 mg) for an average 10 years of treatment does not lower total risk of, breast, colorectal, or other site-specific cancers.[260]

Despite proven benefit, the absolute risk of recurrent vascular events among patients taking aspirin remains relatively high, an estimated 8% to 18% after 2 years. Therapeutic resistance to aspirin might explain a portion of this risk[261] although the mechanism is uncertain. The answer is likely a combination of clinical, biologic, and genetic properties affecting platelet function, and the redundancy of platelet activation pathways and receptors may contribute to the problem of aspirin resistance.[261]

Dosages

Randomized trials have demonstrated that aspirin's therapeutic benefits are achieved from a variety of doses (30 to 1500 mg/d) but the optimal daily dose has not been unequivocally determined.[253,262] In general, higher dose regimens (500 to 1500 mg/d) are not associated with significant added benefit, might actually attenuate the antithrombotic effect of aspirin, and have been associated with increased risk of adverse effects.[253,262] Analyses of patients with acute coronary syndromes enrolled in the Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries (GUSTO) IIb and Platelet IIb/IIIa in Unstable Angina: Receptor Suppression Using Integrilin Therapy (PURSUIT) trials failed to demonstrate a significant difference in 6 month outcomes among patients taking low (<150 mg/d) and intermediate (≥150 mg/d) dose aspirin.[263] Based on earlier randomized trial protocols and clinical experience, the initial dose for the acute management of patients presenting with ACS should be between 162 and 325 mg.[264] Although some trials have used enteric-coated aspirin for initial dosing, more rapid buccal absorption occurs with nonenteric formulations. Given the dose-related risks of bleeding, it is desirable to use a lower dose during the chronic phase of management of ischemic heart disease—typically, enteric-coated preparations of 75 to 162 mg are prescribed.[264]

Side Effects and Contraindications

Aspirin can cause minor bleeding but rarely causes major bleeding except in subjects with coagulopathies or in those who are being treated with other anticoagulants (i.e., warfarin).[264] Use of aspirin is associated with a small increase in the incidence of hemorrhagic stroke in healthy men, but in secondary prevention trials, aspirin reduces the overall

Table 5–9 Current Antithrombotic/Antiplatelet Recommendations from the AHA/ACC Guidelines for Unstable Angina/Non–ST-Segment Elevation MI

	Agent	Recommendation Level	Other
Antiplatelet agents	Aspirin	IA	
	Clopidogrel	IA	
	GP IIb/IIIa	Eptifibatide-IA Tirofiban-IA Abciximab-IA	Abciximab is not indicated (IIIA) without cardiac catheterization

Circulation 2005;111:2699-710.

incidence of stroke. The side effects of aspirin are primarily gastrointestinal, dose related, and ameliorated by using low doses (75 to 162 mg per day). Aspirin use can also lead to gastric erosions, hemorrhage, and ulcers that can contribute to anemia.[264] Reinforcing these observations, a study combined 31 clinical trials to compare the risk of hemorrhage in the setting of low (<100 mg), moderate (100 to 200 mg), and high (>200 mg) doses of aspirin.[265] Low-dose aspirin was associated with the lowest risk, and moderate doses caused a relatively high hemorrhagic event rate—especially with regard to minor, gastrointestinal, total bleeding, and stroke.[265]

Aspirin Resistance

The concept of therapeutic aspirin resistance originated because the immediate biologic effects of aspirin are not uniform among all subjects. Variability in aspirin-mediated platelet inhibition has subsequently been documented among normal subjects, in patients with cerebrovascular disease, stable coronary artery disease, and in those presenting for coronary artery bypass surgery.[261] Despite the apparent consistency of these observations, the exact prevalence of aspirin resistance remains uncertain. The absence of standardized diagnostic criteria or a single validated method of identifying affected individuals has lead to a wide range of population estimates.[261] However, the fact that biochemical measures of aspirin nonresponsiveness have been documented in a wide range of patient populations does not necessarily mean that it has a causal association with cardiovascular disease.

Thienopyridines

Mechanisms of Action

The thienopyridine derivatives, ticlopidine and clopidogrel, are inhibitors of ADP-induced platelet aggregation. The antiplatelet effect of thienopyridine derivatives is due to irreversible inhibition of ADP binding to platelet purinergic receptors (Fig. 5–7).[266-268] Ticlopidine and clopidogrel are inactive in vitro and must be administered in vivo to exhibit antiaggregatory and antithrombotic activities. An active metabolite can be generated from human liver microsomes incubated with clopidogrel.[266] Metabolism of clopidogrel by the hepatic cytochrome P450 enzyme system to an active metabolite[266,267] is essential for its in vivo antiplatelet effects.[266,267] This metabolite of clopidogrel displays the same in vivo effects as seen in vitro, such as inhibition of adenylyl cyclase and inhibition of ADP-induced aggregation.[266,267] Both drugs are mechanistically and structurally similar; however, owing to a higher incidence of severe neutropenia and other adverse effects associated with ticlopidine, clopidogrel has become the primary thienopyridine derivative used in clinical settings.[269]

Indication

Over the past several years, the indications for clopidogrel in patients with ischemic heart disease continue to expand. The effects of a daily dose of clopidogrel (75 mg) have been compared with those of a daily dose of aspirin (325 mg) in individuals at risk for ischemic events. Long-term administration of clopidogrel to patients with atherosclerotic vascular disease is more effective than aspirin in reducing the combined risk of ischemic stroke, myocardial infarction, or vascular death.[269] Both drugs were equally as effective in the prevention of vascular ischemic events in patients who had recently suffered from a myocardial infarction or ischemic stroke. In individuals who had symptomatic atherosclerotic peripheral arterial disease, however, clopidogrel was more effective than aspirin at reducing the incidence of vascular ischemic events. Adding clopidogrel to aspirin within the first 30 days and later (31 days to 12 months) in patients with acute myocardial infarction reduced the risk of ischemic vascular events with benefit emerging within 24 hours of initiation of treatment and continuing throughout the 12 months (mean 9 months) of the study.[270] The benefit of clopidogrel demonstrated in the CURE trial is consistent in low-, intermediate-, and high-risk patients with acute coronary syndromes (as stratified by TIMI risk score), thus supporting its use in patients with documented non–ST-segment elevation acute coronary syndromes.[271] In patients with acute coronary syndrome receiving aspirin, a strategy of a loading dose of clopidogrel followed by long-term maintenance therapy is beneficial in reducing major cardiovascular events, compared with placebo.[258] Clopidogrel has also been shown to be protective when used as an adjunct to fibrinolysis without a significant increase in major bleeding.[272]

With the success of clopidogrel, other thienopyridines are being developed. Prasugrel (CS-747, LY640315), a novel potent thienopyridine $P2Y_{12}$ receptor antagonist, has the potential to achieve higher levels of inhibition of ADP-induced platelet aggregation than currently approved doses of clopidogrel.[273] In a phase 2 study, when administered at the time of percutaneous coronary intervention, prasugrel and clopidogrel both resulted in low rates of bleeding.[274]

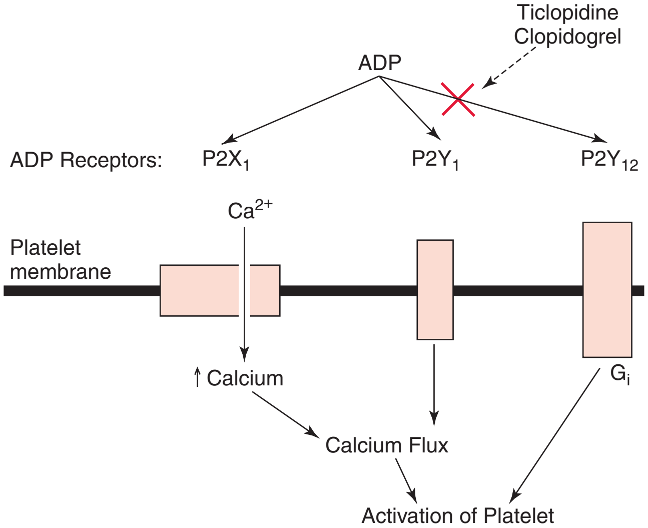

Figure 5–7 **Platelet activation by ADP.** Three receptors that can be activated by ADP are present in the platelet. These are G-protein–coupled receptors and they mediate different responses. The $P2Y_{12}$ receptor is the target for the antiplatelet thienopyridine derivatives, ticlopidine and clopidogrel.

Dosages

The standard dose of ticlopidine is 250 mg twice daily when used as an antithrombotic agent in patients with claudication, unstable angina, peripheral artery bypass surgery, and cere-

brovascular disease. Most studies of clopidogrel have used 300 mg immediately followed by 75 mg once daily.[256,270] As a result of the CURE trial, the FDA approved the 300 mg loading dose of clopidogrel because of the reduction in adverse cardiovascular events with dual antiplatelet therapy in acute coronary syndromes,[275] however, the precise loading dose and timing needed to achieve adequate anticoagulation continue to be areas of investigation. For low-to-intermediate risk patients treated with a 600-mg loading dose of clopidogrel before PCI, incremental clinical benefit within the first 30 days for pretreatment >2 to 3 hours was not evident.[276] It is unclear whether 600 mg results in additional and/or quicker antiplatelet effects because both the 300- and 600-mg loading doses appear to achieve the same degree of maximal platelet inhibition.[275] The safety of loading doses of clopidogrel greater than 600 mg also needs to be evaluated more rigorously before it can be recommended for routine use.[277]

Side Effects and Contraindications

Treatment with ticlopidine is associated with a high incidence of neutropenia (1%), which is usually reversible on discontinuation of treatment; however, in a few cases, it is irreversible and potentially fatal.[278] Patients must be periodically monitored, especially in the first 3 months of treatment, to detect this serious complication. Another potentially life-threatening complication of ticlopidine therapy is thrombotic thrombocytopenic purpura. Clopidogrel represents an advance in antiplatelet therapy because, compared with ticlopidine, its use is not complicated by neutropenia. It must be noted, however, that thrombotic thrombocytopenic purpura is still a harmful, albeit very rare, complication of clopidogrel treatment.[278]

The additional bleeding risk of thienopyridines appears to be dependent on the clinical setting. The risk of major bleeding has been shown to be increased among patients treated with clopidogrel.[256] Much of the debate centers around the increased bleeding noted among patients treated with clopidogrel who subsequently require surgery. In the CURE trial, the overall benefits of starting clopidogrel on admission appear to outweigh the risks, even among those who proceed to bypass surgery during the initial hospitalization.[257] However, it has been clearly shown that preoperative clopidogrel exposure increases the risk of reoperation and the requirements for blood and blood product transfusion during and after coronary bypass surgery.[279]

Current available data show that about 4% to 30% of patients treated with conventional doses of clopidogrel do not display an adequate antiplatelet response. The optimal level of clopidogrel-induced platelet inhibition, which will correlate quantitatively with clopidogrel's ability to prevent atherothrombotic events, is still not definitely known. In addition, because there is no validated platelet function assay to measure clopidogrel's antiplatelet effect, it is not justified to routinely measure clopidogrel resistance in the clinical setting.[280] The clinical implications of this variability are unknown but potentially are important. Future clinical trials may define whether hyporesponders to clopidogrel are at increased risk for thrombotic events and whether hyperresponders are at increased risk for bleeding. If these data become available, the individualization of antiplatelet therapy, including clopidogrel dosing, may be possible.[265]

Dipyridamole

Mechanisms of Action

Dipyridamole is a platelet inhibitor that is primarily recognized as an antithrombotic agent. In addition, through the generation of adenosine, dipyridamole evokes vasodilation and through the combination of these antiplatelet and vasodilator functions likely improves tissue perfusion. The European Stroke Prevention Study 2 (ESPS-2) demonstrated that treatment with dipyridamole was as effective as low-dose aspirin in the reduction of stroke risk.[281] Because dipyridamole is a weak direct platelet inhibitor, clinical observations such as this suggest that dipyridamole may have additional beneficial vascular effects. Dipyridamole has been reported to have antioxidant properties,[282] but the direct effect on vascular cells is not known. Dipyridamole is also a highly efficient chain-breaking antioxidant with fluorescence that is quantitatively quenched on reaction with peroxyl radicals.[282] Consistent with these observations, treatment with dipyridamole significantly limits ischemia-reperfusion injury in humans in vivo.[283]

Indication

Analysis using data from ESPS-2 has shown that, compared with aspirin alone, aspirin plus extended-release dipyridamole is efficacious in reducing the risk for stroke and vascular events among patients younger than 70 years; those with hypertension, prior stroke, or transient ischemic attack; current smokers; and those with any history of cardiovascular disease. Relative hazard reductions favored the combination of aspirin plus extended-release dipyridamole and were greatest for the high-risk patients.[284] Analysis of randomized controlled trials involving dipyridamole in patients with previous ischemic stroke or TIA showed that dipyridamole, given alone or with aspirin, reduces stroke recurrence in patients with previous ischemic cerebrovascular disease. The combination of aspirin and dipyridamole also reduces the composite of nonfatal stroke, nonfatal myocardial infarction, and vascular death when compared with aspirin alone.[285] However, most of these conclusions are based on a single trial and only in patients presenting after cerebral ischemia.

Dosages

A standard dose of dipyridamole is 200 mg plus acetylsalicylic acid 25 mg.[286] The first European Stroke Prevention Study (ESPS-1) which found the combination of aspirin/dipyridamole to be superior to placebo in the prevention of stroke and transient ischemic attack (TIA) evaluated dipyridamole 75 mg three times per day. The ESPS-1, however, did not include an aspirin-only treatment arm and, therefore, it was unclear whether the combination of aspirin/dipyridamole was superior to aspirin alone. As a result, a second trial was conducted that included treatment arms of aspirin alone, extended release dipyridamole alone, combination therapy, and placebo. The combination of aspirin 25 mg plus extended release dipyridamole 200 mg twice daily was shown in the ESPS-2 to be significantly better than either agent given individually in preventing stroke.[281]

Side Effects and Contraindications

Peak plasma concentrations are achieved after approximately 2 hours following oral administration of dipyridamole (200 mg

twice daily).[287] Although dipyridamole is highly lipophilic, it does not cross the blood-brain barrier to a significant degree. Dipyridamole is metabolized in the liver where it is conjugated and excreted through the bile into the feces.[287] Adverse events noted in ESPS-2 included mild gastrointestinal problems as well as infrequent serious bleeding.[281] The addition of dipyridamole to aspirin appeared to result in a bleeding risk similar to that of aspirin alone.[281] A contraindication for dipyridamole is for known hypersensitivity to the drug. As far more individuals have sensitivity to aspirin, care should be taken when giving Aggrenox, an aspirin/dipyridamole combination medication. Dipyridamole is excreted in breast milk and should be used with caution in nursing mothers.

Glycoprotein IIb/IIIa Receptor Antagonists

Mechanisms of Action

The GP IIb/IIIa receptor serves as a bidirectional conduit with GP IIb/IIIa-mediated signaling occurring immediately after the binding of fibrinogen and initiating intracellular signaling that further stabilizes the aggregate (Fig. 5–8). Calcium mobilization, tyrosine phosphorylation, activation of phosphoinositide metabolism, and cytoskeletal reorganization result from the activation of the GP IIb/IIIa complex. This series of events transforms platelet aggregation from a reversible to an irreversible process.

Although aspirin and clopidogrel are effective antiplatelet agents, they are relatively weak antiaggregatory drugs. Drugs that specifically target the GP IIb/IIIa receptor and prevent the binding of fibrinogen inhibit this final common pathway for platelet aggregation.[288] Platelet aggregation is completely inhibited by blockade of 80% of the surface GP IIb/IIIa receptors,[289] and antagonism of the GP IIb/IIIa receptor inhibits platelet aggregation, irrespective of the platelet activator. Multiple clinical trials have shown inhibition of GP IIb/IIIa to be a highly effective antithrombotic strategy.[290] There are several classes of GP IIb/IIIa inhibitors in clinical use. Abciximab is a Fab fragment of the 7E3 antibody that has high affinity and a slow rate of dissociation from GP IIb/IIIa. In contrast, the small molecules, eptifibatide and tirofiban, have a much more rapid rate of dissociation.

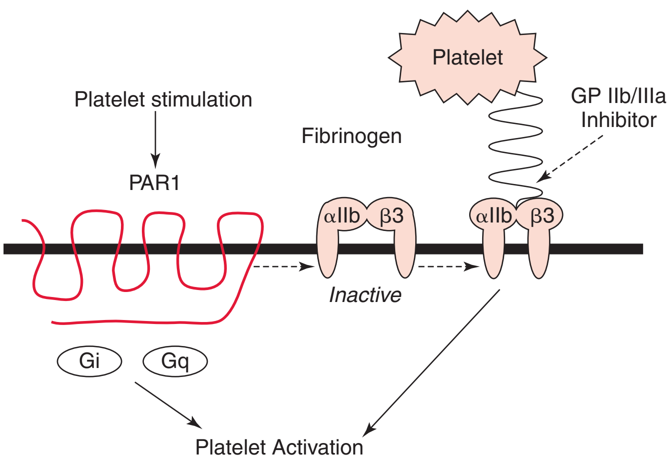

Figure 5–8 **Platelet aggregation and fibrinogen binding to glycoprotein IIb/IIIa.** Damage or vascular injury exposes subendothelial von Willebrand factor (VWF) or collagen to the circulating blood. Platelets adhere and events cause a conformational change in glycoprotein (GP) IIb/IIIa enabling the high affinity binding of fibrinogen which results in thrombus formation. This process can be attenuated by GP IIb/IIIa inhibitors.

Indications

Evidence supports the use of GP IIb/IIIa antagonists in patients with unstable angina/NSTEMI undergoing coronary intervention.[291-293] Current ACC/AHA Guideline Committee recommendations advise that high-risk patients, especially troponin-positive patients, should receive a GP IIb/IIIa antagonist. The small-molecule agents, eptifibatide and tirofiban, may be started 1 to 2 days before and continued during the procedure. Any of the GP IIb/IIIa antagonists may be started immediately before or during the procedure. None of the GP IIb/IIIa antagonists appears to be effective in the routine management of low-risk, troponin-negative patients in whom early coronary intervention is not planned.

The use of GP IIb/IIIa inhibitors in patients not undergoing coronary intervention is less clear. The small-molecule GP IIb/IIIa antagonists eptifibatide and tirofiban appear to modestly reduce the combined endpoint of death or myocardial infarction with some increase in bleeding.[294] As shown by a meta-analysis, the patients who underwent early revascularization appeared to derive the greatest benefit.[294] The use of abciximab in patients with UA/NSTEMI in whom intervention is not planned is not indicated based on the results of the GUSTO IV-ACS trial.[295]

Oral Glycoprotein IIb/IIIa Receptor Antagonists

Several ligands of integrins, including fibrinogen and von Willebrand factor, possess one of the two amino acid sequences 95-97 (Arg-Gly-Asp or RGD) and 572-575 (Arg-Gly-Asp-Ser or RGDS) that enable them to bind to the activated GP IIb/IIIa receptor and inhibit platelet aggregation.[296] These nonpeptide mimetics are unique in that they have the potential for oral administration that initially was thought to be useful for long-term antiplatelet therapy; however, several oral GP IIb/IIIa inhibitors have been evaluated, and their use has not been associated with clinical benefit.[297-300] Reasons for this discrepancy are unclear, and potential explanations have included hypothetical partial agonist activity, a prothrombotic effect of the oral compounds, or a direct toxic effect that is unrelated to platelet activation such as apoptosis.[301-303] Additionally, there has been the observation that some oral GP IIb/IIIa inhibitors augment small platelet microaggregate formation following stimulation.[302,303]

Dosages

The dose of GP IIb/IIIa antagonist depends on the specific agent being used. For abciximab, a bolus dose of 0.25 mg/kg followed by a 12-hour infusion at 0.125 μg/kg/min (to a maximum of 10 μg/min) with unfractionated heparin before the procedure is efficacious for patients undergoing coronary intervention.[304] For ongoing angina before intervention, a bolus of 0.25 mg/kg 18 to 24 hours before the procedure followed by a continuous infusion of 10 μg/min until 1 hour after the procedure (with heparin) has been used.[305]

Although lower doses have been used for percutaneous coronary interventions, eptifibatide is given as a double

bolus of 180 μg/kg (10 minutes apart) with an infusion of 2 μg/kg/min.[306] In unstable angina/NSTEMI, a 180 μg/kg bolus of eptifibatide is used followed by a 2 μg/kg/min infusion.[307] The infusion rate should be decreased by 50% in patients with a creatinine clearance of less than 50 mL/min.

Tirofiban is used as a bolus of 0.4 μg/kg/min over 30 minutes followed by an infusion of 0.1 μg/kg/min; it should be administered with heparin.[307] The infusion rate should be reduced by 50% in patients with a creatinine clearance of less than 30 mL/min.

Side Effects and Contraindications

The primary adverse reactions to GP IIb/IIIa receptor antagonists are bleeding and thrombocytopenia. Immune mechanisms responsible for the thrombocytopenia have been identified for all of the agents currently available in the United States. Although the overall incidence is relatively low, the effects may be life threatening. Thrombocytopenia with abciximab (as defined by a platelet count $<100 \times 10^9$/L) occurs in 2.5% to 6% of patients and severe thrombocytopenia (platelet count $<50 \times 10^9$/L) occurs in 0.4% to 1.6% of patients in reported clinical trials. Platelet transfusions were administered to 0.9% to 6% of patients in this setting.[290,308] Readministration of abciximab does not appear to have an enhanced risk when compared with primary exposure; however, the severity in those who develop thrombocytopenia may be greater.

Thrombocytopenia with eptifibatide is reported to occur between 1.2% and 6.8% of patients and platelet transfusions have been reported to be needed in 1.3% to 1.5% of patients.[306,309] Thrombocytopenia with tirofiban is reported to occur in 1.1% to 1.9% of patients with severe thrombocytopenia occurring in 0.2% to 0.5%.[307] It is important to note that treatment with these agents can also cause pseudothrombocytopenia, which occurs as a result of artifactual platelet clumping in vitro, yielding a falsely decreased platelet count. This observation may be dependent on the use of specific anticoagulants for the assays including citrate, ethylenediaminetetraacetic acid (EDTA), or nonchelating anticoagulants. The incidence of pseudothrombocytopenia may be as high as 2.1% with the use of abciximab. A smear to directly examine for the presence of clumped platelets may be required.

Thrombin Inhibitors

The standard antithrombotic agents are unfractionated heparin (and now low-molecular-weight heparin, LMWH) and warfarin. Owing to the limitations of these drugs, the evolution of antithrombotic treatment for cardiovascular disease has continued with the emerging importance of therapies focused on improved dosing and decreased laboratory monitoring, as well as enhanced efficacy and safety profiles. New antithrombotic strategies continue to evolve in three general directions. The best studied approach has been the development of direct inhibitors of specific coagulation factors. Direct inhibitors of thrombin (i.e., factor IIa) and factor Xa, two serine proteases with central roles in the coagulation cascade, have undergone clinical trials to define their role as adjuncts to thrombolysis and their use in preventing thrombosis after interventional cardiovascular procedures.

A second approach has been the production of recombinant endogenous anticoagulants including recombinant thrombomodulin. This also involves recombinant forms of antithrombin III and heparin cofactor II, which are serine protease inhibitors that interact with the glycosaminoglycan cofactors, heparin, heparan sulfate, and dermatan sulfate to inhibit coagulation factors. Another strategy is manipulation or synthetic production of endogenous, natural anticoagulant cofactors. This includes modification of native glycosaminoglycans, such as heparan sulfate, dermatan sulfate, or the heparin pentasaccharide, to enhance their anticoagulant activity.

Unfractionated Heparin

Mechanisms of Action

Almost all heparin preparations are extracted from porcine intestinal mucosa or bovine lung and consist of both high-molecular-weight and low-molecular-weight fractions. The high-molecular-weight fraction (average molecular mass, 20 kD) comprises 66% of a given preparation by mass, has a weak anticoagulant effect, and can activate platelets. The low-molecular-weight fraction (average molecular mass, 7 kD) represents approximately 33% of a given preparation, possesses 85% of the total anticoagulant activity of the original sample, and causes little platelet activation. The low-molecular-weight and high-molecular-weight fractions are each characterized by subspecies with low and high affinities for antithrombin III. The heparin species with high affinity for antithrombin III possesses a critical pentasaccharide sequence that mediates this interaction. The low-molecular-weight heparin fraction with high affinity for antithrombin III represents that fraction with the most potent anticoagulant activity and the least platelet-stimulating activity.

Indications

Unfractionated heparin has been used in the management of unstable angina/NSTEMI for many years, and its benefit when added to aspirin has been clearly established.[291] In addition, many of the platelet inhibitor trials have been conducted with the coadministration of heparin. This has established heparin as a class IA therapy when used with platelet inhibitors.

The use of heparin as an adjuvant with fibrinolysis has also been examined in clinical trials. The use of subcutaneous or intravenous heparin as an adjunct to streptokinase remains controversial. Heparin is, however, recommended in streptokinase-treated patients who are at high risk of thrombosis.[310] Patients with STEMI who are receiving tPA should also be given heparin (as a 60 U/kg IV bolus maximum 4000 U at the time of initiating the tPA infusion, with an initial maintenance infusion of 12 U/kg/hr at a maximum of 1000 U/hr to maintain the aPTT at 1.5 to 2 times the control rate).[310] A 48-hour infusion is likely to be sufficient if aspirin is being given, and IV heparin therapy should be sustained only if there appears to be a high risk of systemic embolism such as a large anterior MI, CHF, previous systemic embolus, or atrial fibrillation. Otherwise, only low-dose heparin therapy (7500 U SC every 12 hours) is indicated as temporary prophylaxis against venous thrombosis. It has been suggested that a similar approach may be used for patients who have received reteplase or tenecteplase (TNK).[310]

Dosages

Heparin is cleared through a combination of a rapid saturable mechanism and a much slower mechanism with first-order mechanics. The slower, unsaturable mechanism of clearance is largely renal. These kinetics make the anticoagulant response to heparin nonlinear at therapeutic doses, with both the intensity and duration of effect rising disproportionately with increasing dose. Thus, the apparent biological half-life of heparin increases from 30 minutes after an IV bolus of 25 U/kg to 60 minutes with an IV bolus of 100 U/kg and 150 minutes with a bolus of 400 U/kg.[311-313] In patients with unstable angina, the dose of heparin is usually adjusted to maintain aPTT at an intensity equivalent to a heparin level of 0.2 to 0.4 U/mL as measured by protamine titration or by an anti-factor Xa level of 0.30 to 0.7 U/mL. For many aPTT reagents, this is equivalent to a ratio (patient/control aPTT) of 1.5 to 2.5.[311-313] As noted, heparin is normally administered with an initial 60 U/kg (maximum 4000 U) IV bolus, followed by IV infusion of 12 U/kg/hr (maximum 1000 U/hr), adjusted to maintain the aPTT at 1.5 to 2.0 times the control value. Treatment is usually initiated within 24 hours after the onset of chest pain.[311-313]

Side Effects and Contraindications

The primary side effect associated with the use of unfractionated heparin is bleeding. The risk of bleeding with IV unfractionated heparin is <3% in recent trials.[314] This bleeding risk increases with higher heparin dosages, concomitant use of antiplatelet drugs or oral anticoagulants, and increasing age (>70 years).[314]

Another problem associated with heparin is the development of heparin-induced thrombocytopenia (HIT), usually developing between 5 and 15 days after the initiation of heparin therapy. A more rapid onset form may occur in patients who have previously been exposed to heparin. HIT occurs when heparin binds to platelets, leading to platelet activation and the release of platelet factor 4. Antibodies are generated against the heparin/platelet factor 4 complex. The thrombosis associated with this syndrome may be due to immune-mediated platelet activation and microparticle formation. In the setting of HIT, an alternative antithrombin drug must be selected, and several have been approved by the FDA specifically for this use. Less commonly, long-term use of heparin is also associated with the development of osteoporosis and rare allergic reactions.

Low-Molecular-Weight Heparin

Mechanisms of Action

The use of unfractionated heparin has several limitations that include nonspecific binding, the production of antiheparin antibodies that may induce thrombocytopenia, continuous intravenous infusion, and the need for frequent monitoring. Because of the many known limitations associated with the use of unfractionated heparin, LMWHs have been developed. Issues such as continuous IV infusion and frequent monitoring are not problems normally encountered with the use of LMWHs. LMWHs are potent inhibitors of both thrombin (anti-IIa effects) and factor Xa. LMWHs can be given by subcutaneous administration and have a rapid and predictable absorption. The LMWHs also produce fewer platelet agonist effects and are less often associated with heparin-induced thrombocytopenia. These advantages have been well demonstrated in patients with venous disease and are now emerging for those with unstable angina.[310]

Indications

LMWHs have been studied in the treatment of ST-elevation myocardial infarction (STEMI) and in patients receiving fibrinolysis. Although the data have been mixed, in a number of trials evaluating its use in STEMI, LMWH has been found to have improved efficacy as compared with unfractionated heparin. A meta-analysis from the Efficacy and Safety of Subcutaneous Enoxaparin in Non-Q-Wave Coronary Events (ESSENCE) and the Thrombolysis in Myocardial Infarction (TIMI) 11B studies has shown that enoxaparin is superior to unfractionated heparin in reducing the composite endpoints of death, myocardial infarction, and emergency revascularization in patients with Q-wave myocardial infarction.[315,316] A subsequent meta-analysis by Petersen and coworkers that pooled the data from six trials of enoxaparin in non–ST-segment elevation ACS showed significant reductions in death/MI by 30 days, especially in patients who had not received any antithrombin before randomization.[317] In contrast, the observations with other LMWHs, including dalteparin and fraxiparine, have been less encouraging. This may be due to enoxaparin's greater anti-Xa-to-anti-IIa ratio when compared with dalteparin, the greater severity of illness in the patients enrolled in the reported studies, and the extension of its antithrombotic actions to include inhibition of platelet aggregation by suppression of the release of von Willebrand factor.[318] The ACC/AHA guidelines suggest that enoxaparin, but not the other LMWHs, is preferred over unfractionated heparin for the medical management of UA/NSTEMI unless coronary artery bypass grafting (CABG) surgery is planned within 24 hours (Class IIa recommendation). Patients with elevated troponin values may derive the greatest benefit.

The current ACC/AHA guidelines also state that it is reasonable (Class IIb) to consider a LMWH as an alternative to unfractionated heparin in patients receiving fibrinolytic therapy who are <75 years of age and free of renal dysfunction.[292] Clinical trials have also demonstrated similar safety with LMWHs when compared with unfractionated heparin in the setting of PCI and in conjunction with glycoprotein IIb/IIIa inhibitors. Further study is needed to define the benefit of LMWHs in relevant high-risk subgroups before their use can be universally recommended (see Chapter 11 for further discussion).[319]

Dosages

In the setting of fibrinolysis, enoxaparin is given as a 30-mg intravenous bolus before fibrinolytic administration. Enoxaparin at a dose of 1 mg/kg subcutaneously is given twice daily for 48 hours.[320,321] The dosing regimen should be changed to 1.0 mg/kg subcutaneously every 24 hours for patients with an estimated creatinine clearance of <30 mL/min. Typically, the enoxaparin regimen is maintained for the duration of the hospitalization or day 8, whichever comes first. Continuing therapy after discharge has not shown benefit.[320,321]

In the setting of PCI, enoxaparin has been administered in several ways.[320,321] The first dosing regimen option is 1 mg/kg subcutaneously twice daily. When this route is used, it is important to ensure that the last dose of subcutaneous LMWH is administered within 8 hours of the procedure and that at least 2 subcutaneous doses of LMWH are given before

the procedure to ensure steady state. The second dosing regimen option is 1 mg/kg subcutaneously twice daily plus 30 mg intravenously at the time of PCI. This regimen can be used if >8 hours has passed since the last subcutaneous dose of enoxaparin. The third dosing regimen option is 1 mg/kg enoxaparin intravenously (if no GP IIb/IIIa inhibitor is used) or 0.75 mg/kg (if a GP IIb/IIIa inhibitor is used) at the time of PCI.[320,321] For elective PCI, an intravenous dose of 0.5 mg/kg was found to be safe in the STEEPLE study.[321a]

Side Effects and Contraindications

As with unfractionated heparin, LMWH should not be given to patients with contraindications to anticoagulant therapy such as active bleeding, significant thrombocytopenia, recent neurosurgery, intracranial bleed, or ocular surgery. Caution should be exercised in patients with bleeding diathesis, brain metastases, recent major trauma, endocarditis, and severe hypertension. LMWH is associated with less major bleeding compared with UFH in acute venous thromboembolism. UFH and LMWH are not associated with an increase in major bleeding in ischemic coronary syndromes, but are associated with an increase in major bleeding in ischemic stroke.[314] Patients treated with LMWH can develop HIT, and these drugs are not recommended for use in patients with documented or suspected HIT. Patients with renal dysfunction (usually defined as serum creatinine level >2 [in men] or 2.5 [in women] mg/dL) have been excluded from major studies of enoxaparin. Appropriate dosing in obese patients is unclear and is a current area of investigation.

Direct Thrombin Inhibitors

Direct thrombin inhibitors block thrombin's substrate interactions and inactivate fibrin-bound thrombin and fluid-phase thrombin. Direct thrombin inhibitors do not bind to plasma proteins or to platelet factor 4.[322]

Hirudin (lepirudin)

Mechanisms of Action

Hirudin is a polypeptide found in the salivary glands of the leech *Hirudo medicinalis,* and it is among the most potent of the natural thrombin inhibitors. Various biochemical and molecular biological techniques have been used to study the specific nature of the hirudin-thrombin interaction. The aminoterminal region of hirudin binds via hydrophobic interaction with the apolar binding site of thrombin. The carboxyterminal region appears to bind ionically to the anion binding exosite of thrombin. Direct interaction of hirudin with both the catalytic site and the anion binding exosite of thrombin probably accounts for its potent inhibition of all thrombin-mediated reactions, and this inhibition is equipotent toward free and fibrin-bound thrombin. The most commonly used measures for the anticoagulant activity of hirudin are the thrombin time (TT) and the activated partial thromboplastin time (aPTT). Hirudin does not have direct effects on platelet aggregation or secretion, and the bleeding time is not altered significantly.

Indications and Dosages

Both the TIMI-9 and the Global Utilization of Strategies to Open Occluded Coronary Arteries (GUSTO) II trials compared a single dose of heparin with a single dose of hirudin.[323] Both trials initially used high doses of hirudin (0.6 mg/kg bolus followed by 0.2 mg/kg/hr) and weight-adjusted heparin, and both trials were terminated prematurely because of an unacceptably high rate of intracerebral hemorrhage in both treatment arms. These trials were continued as TIMI-9b and GUSTO IIb, using lower doses of both hirudin (0.1 mg/kg bolus followed by 0.1 mg/kg/hr) and heparin (not weight adjusted). Results from the TIMI-9b trial showed heparin and hirudin to be equally effective as adjunctive therapies for streptokinase or t-PA in individuals with acute Q-wave myocardial infarction, without a difference in bleeding events.[324] Results of the GUSTO IIb trial[325] showed a marginally significant benefit of hirudin over heparin early after infarction in individuals with both Q wave and non–Q-wave myocardial infarction; however, this effect lessened over time.

Results from the Organisation to Assess Strategies for Ischemic Syndromes (OASIS-2) trial suggest that recombinant hirudin may be useful when compared with heparin in preventing cardiovascular death, myocardial infarction, and refractory angina with an acceptable safety profile in patients who have unstable angina or acute myocardial infarction without ST elevation and who receive aspirin.[326] In this study, 10,141 patients with unstable angina or acute myocardial infarction without ST elevation were randomly assigned heparin (5000 units bolus then 15 U/kg/hr; n = 5058) or hirudin (0.4 mg/kg bolus then 0.15 mg/kg/hr infusion; n = 5083) for 72 hours. At 7 days, 213 (4.2%) patients in the heparin group and 182 (3.6%) in the hirudin group had experienced cardiovascular death or new myocardial infarction (relative risk 0.84 [95% CI 0.69 to 1.02]; P = 0.077).[326]

An approved clinical application for recombinant hirudin (lepirudin) is in the treatment of HIT. When compared with historical controls, lepirudin-treated patients had consistently lower incidences of combined endpoints primarily because of a reduced risk for new thromboembolic complications. During treatment with lepirudin, aPTT ratios of 1.5:2.5 produce optimal clinical efficacy with a moderate risk for bleeding, aPTT ratios lower than 1.5 are subtherapeutic, and aPTT levels greater than 2.5 are associated with high bleeding risk. Bleeding events that require transfusion were significantly more frequent in patients taking lepirudin than in historical control patients. Lepirudin has also been used for anticoagulation in patients treated with extracorporeal circulation during open heart surgery. Comprehensive data on this group of patients, however, are lacking.

Dosages

Hirudin is used in the dosages discussed earlier. It has a narrow therapeutic window and requires monitoring, particularly when it is administered with thrombolytic agents. It is often given as a 0.4 mg/kg bolus, followed by a 0.15 mg/kg/hr infusion for 72 hours to maintain the aPTT between 60 and 100 seconds.

Side Effects and Contraindications

Hirudin should not be used in settings where anticoagulation is contraindicated. The risk of bleeding with hirudin is increased in the setting of concomitant anticoagulation or platelet inhibitors. Hirudin is renally cleared and should not be used in patients with renal dysfunction.

Argatroban

Mechanisms of Action

Another potent direct thrombin inhibitor is (*2R,4R*) 4-methyl-[N^{2-}(3-methyl-1,2,3,4-tetrahydro-8-quinolinyl) sulfonyl]-2-piperidine carboxylic acid, or argatroban. This compound is a synthetic N^2-substituted arginine derivative that binds to the catalytic site of thrombin with high affinity. It binds rapidly and reversibly to both clot-bound and soluble thrombin. Argatroban has a relatively short elimination half-life (39 to 51 minutes) and its reversible binding allows for rapid restoration of normal hemostasis on cessation of therapy. Argatroban has a predictable dose response that correlates with changes in anticoagulant parameters.

Indications

Studies with argatroban primarily have assessed its use as adjunctive therapy with fibrinolytics, in the treatment of HIT, or in patients undergoing coronary angioplasty. Data with argatroban are limited and it is approved only for use in HIT. Argatroban causes a dose-dependent increase in aPTT and TT. The half-life of the anticoagulant effect is approximately 25 minutes when argatroban is used alone.

For patients with HIT who are administered intravenous argatroban, benefit is noted as compared with historical controls. In HIT patients, argatroban therapy, compared with historical controls, improves outcomes, particularly new thrombosis and death caused by thrombosis.[327]

Dosages

In individuals with unstable angina, argatroban (0.5 to 5.0 μg/kg/min for 4 hours) is administered. For patients with HIT, argatroban, 2 μg/kg/min, is adjusted to maintain the activated partial thromboplastin time at 1.5 to 3 times the baseline value for a mean of 5 to 7 days.

Side Effects and Contraindications

Patients who have contraindications to anticoagulant therapy, as previously discussed, should avoid using argatroban. Argatroban is metabolized by the liver. In patients with hepatic impairment, the maximum concentration and half-life of argatroban are increased approximately two- to three-fold and clearance is one fourth that of healthy volunteers.

Bivalirudin (Hirulog)

Mechanisms of Action

Hirudin-derived thrombin inhibitors known as hirulogs are synthetic peptides that contain the two distinct domains of hirudin with antithrombin activity. Hirulog-1 (bivalirudin) contains a thrombin active-site inhibitory fragment, D-Phe-Pro-Arg-Pro, and a thrombin anion binding exosite recognition sequence that is analogous to hirugen. These fragments are joined by a glycine spacer at least four residues in length. Subtle modifications of hirulogs can increase their affinity for thrombin to a level equal to that of native hirudin.

Indications

Bivalirudin has been investigated in STEMI with streptokinase but was associated with excess bleeding. In individuals undergoing coronary angioplasty, bivalirudin was efficient in preventing abrupt closure and was found to be safe. In addition, among individuals undergoing percutaneous transluminal coronary angioplasty for unstable or post-infarction angina, bivalirudin was as effective as heparin but was associated with lower rates of moderate bleeding. Although bivalirudin reduces ischemic complications and bleeding after PCI, further trials are needed to evaluate bivalirudin versus heparin in conjunction with clopidogrel, GP IIb/IIIa inhibitors, and current standards of coronary intervention.[328] The current recommended dose of bivalirudin in the setting of PCI is an intravenous bolus of 0.75 mg/kg followed by an infusion of 1.75 mg/kg/hr for the duration of the procedure. Five minutes after the bolus, an ACT should be measured and an additional 0.3 mg/kg given intravenously as needed. The infusion may be continued for 4 hours after the procedure at the discretion of the operator.

Oral Anticoagulants

Warfarin

Mechanisms of Action

Warfarin and coumarin derivatives are vitamin K antagonists that prevent the cyclic interconversion of vitamin K and its 2,3-epoxide. Vitamin K is a cofactor for posttranslational carboxylation of glutamic acid residues that are on the amino terminus of vitamin K-dependent coagulation factors including factors II, VII, IX, and X, and anticoagulant proteins (proteins C and S). The antithrombotic properties of coumarin derivatives are delayed for 72 to 96 hours.

Indications

Although standard for the treatment and prevention of venous thrombosis, oral anticoagulant therapy has also been investigated in patients with ischemic heart disease. Warfarin, in combination with aspirin or given alone, was superior to aspirin alone in reducing the incidence of composite events after an acute myocardial infarction but was associated with a higher risk of bleeding.[329] In this study (WARIS II), the combination therapy targeted an international normalized ratio (INR) of 2–2.5 and the warfarin alone group had a target INR of 2.8–4.2.

Using a fixed, low dose of warfarin added to aspirin in the long term after myocardial infarction did not demonstrate reduction in the combined risk of cardiovascular death, reinfarction, or stroke. A fixed, low dose of warfarin added to aspirin reduced the risk of stroke, but this was a secondary endpoint. The combination of aspirin and warfarin was also associated with an increased risk of bleeding.[330]

Although the studies have been mixed, current available data based on nearly 20,000 patients participating in randomized clinical trials demonstrate that, when given in adequate doses, oral anticoagulants reduce the rates of reinfarction and thromboembolic stroke—but they do so at the cost of increased rates of hemorrhagic events.[331] However, the use of warfarin, even in controlled trials, is fraught with difficulties, as in the WARIS II study, wherein the international normalized ratio (INR) was below target in about one third of patients, and those over 75 years of age were excluded.[331]

Dosages

Dosages of warfarin should be adjusted based on the INR, which in turn is based on the use of an International

Sensitivity Index (ISI) assigned to each thromboplastin reagent so as to standardize the dose.

Side Effects and Contraindications

Oral anticoagulants have a narrow therapeutic window and a highly variable dose-response relation. The most frequent complication of warfarin therapy is the risk of bleeding. The major determinants of vitamin K antagonist-induced bleeding are the intensity of the anticoagulant effect, underlying patient characteristics, and the length of therapy. There is good evidence that vitamin K antagonist therapy with a targeted INR of 2.5 (range, 2.0 to 3.0) is associated with a lower risk of bleeding than is therapy targeted at an INR >3.0.[314]

A rare complication of warfarin therapy is skin necrosis. Warfarin-induced skin necrosis usually develops soon after initiation of therapy and is higher in frequency in patients with protein C or protein S deficiency. Patients with known protein C or S deficiencies should be started on warfarin only after therapeutic doses of heparin have been initiated. Warfarin is also teratogenic and its use should be avoided during pregnancy, although the use of oral anticoagulants versus heparin/LMWH during pregnancy is an ongoing area of investigation.

Oral Thrombin Inhibitors

Warfarin has limitations that are well established and include a narrow therapeutic index, the need for high quality dose management, and interactions with other drugs, foods, and comorbid conditions. In the interest of developing safer and more effective oral anticoagulants, orally active direct inhibitors of thrombin are being investigated with the hopes of replacing the coumarins for the long-term treatment of thromboembolic disorders. Important issues in the profile of the ideal thrombin inhibitor include safety, potency, selectivity, oral bioavailability, and half-life. The furthest along in development has been ximelagatran, an agent that was thought to be promising owing to its rabid absorption, low protein binding, lack of drug interactions, and fixed dose. However, ximelagatran failed to receive FDA approval because of the potential for hepatotoxicity. Other oral thrombin inhibitors are undergoing clinical study.

Fibrinolytics

Fibrinolytic drugs have been incorporated into the standard management of ST-segment elevation myocardial infarction. With these therapies, short-term mortality gains are accompanied by an improvement in ventricular function and a reduction in major cardiovascular complications. Follow-up studies have demonstrated that these short-term gains, after a single fibrinolytic administration, are sustained for at least 8 years. Of note, only about 50% of patients achieve normal epicardial coronary artery flow (TIMI 3) within 90 minutes of administration of tPA or TNK.

Mechanisms of Action

Plasminogen is a proenzyme that is converted to the active enzyme plasmin by plasminogen activators. Plasmin degrades fibrin into soluble degradation products. Plasminogen activators cause thrombus dissolution by initiating this cascade. This process is inhibited by plasminogen activator inhibitors that prevent excessive plasminogen activation by t-PA and urokinase-type plasminogen activator (uPA).

Indications

Fibrinolytic therapy has been used in patients who have had at least 30 minutes of ischemic chest pain and either 1 mm of ST-segment elevation in at least two adjacent limb leads, 2-mm ST-segment elevation in at least two adjacent precordial leads, or complete bundle branch block.[332] Patients should be treated within 12 hours of the onset of symptoms. Most important in terms of survival advantage is the time from the onset of symptoms to the initiation of therapy. There does not appear to be benefit when fibrinolytic therapy is used for unstable coronary syndromes not associated with ST-segment elevation.[333]

Dosages

Streptokinase is usually administered as an intravenous infusion of 1.5 million units over 30 to 60 minutes. Recombinant tissue plasminogen activator is relatively fibrin selective. The most commonly used dose of tPA is administered as a 15 mg bolus over 3 minutes, followed by a 0.75 mg/kg (not to exceed 50 mg) over 30 minutes, and then 0.5 mg/kg (not to exceed 35 mg/kg) over an additional 60 minutes.

Reteplase is a truncated form of tPA that lacks the first Kringle domain. It has a longer half-life as compared with tPA but has not shown superiority over accelerated tPA. It is administered as two intravenous boluses of 10 U given 30 minutes apart with each bolus administered over 2 minutes.

Tenecteplase is a mutated form of tPA that has an extended half-life and greater fibrin specificity. It is equivalent to accelerated tPA and can be given in a single bolus (5 to 10 seconds) in a dose according to body weight: 30 mg to patients who weigh less than 60 kg; 35 mg to those who weigh 60 to 69.9 kg; 40 mg to those who weigh 70.0 to 79.9 kg; 45 mg to patients who weigh 80.0 to 89.9 kg; and 50 mg to patients who weigh 90.0 kg or more.[334]

Side Effects and Contraindications

Bleeding is the major adverse side effect common to fibrinolytic agents. The risk of intracranial hemorrhage averages 0.5% with the relatively fibrin-specific agents; rates of ICH rise to 1% to 2% with increasing patient age. Streptokinase is known to have allergic reactions in approximately 5% of patients, but anaphylaxis is rate.

THROMBOSIS: FUTURE DIRECTIONS

An important lesson that has emerged from the numerous trials aimed at treating acute cardiovascular thrombosis is that increased antithrombotic potency may not guarantee enhanced clinical benefit. It is not known whether this is due to problems with the specific antithrombotic agents, the risk of bleeding, or the inherent limitations of our current means of measuring thrombosis. Novel therapies are also being developed to target alternative and redundant thrombotic pathways including (Table 5–10) new inhibitors of the $P2Y_1$ and $P2Y_{12}$ receptors,[335] the CD40-CD40 ligand system, adhesion molecules, CD39/ATPDase, and the GPIb-V-IX complex–von Willebrand factor.[336] New anticoagulants are being developed that will also address some of the limitations

Table 5–10 Platelet Inhibitors Under Development and Their Mechanism of Action

Therapeutic Agent	Mechanism of Action	
Nitroaspirin (NCX4016)	NO donor[338]	
P2Y12 antagonist (AR-C69931 MX)	Purinergic receptor inhibitor[335]	
VWF-GPIb-IX inhibitors	Inhibit platelet adhesion	
Collagen-GPVI inhibitors	Inhibit platelet adhesion	Inhibit aggregation
Thrombin-platelet inhibitors	Inhibit PAR-1 receptors	Inhibit PAR-4

of the currently available drugs.[1] Direct inhibitors targeting the initiation of coagulation have been studied and include active-site blocked factor VIIa and tissue factor pathway inhibitors. In addition, inhibitors of the propagation of coagulation are being examined including Factor IXa inhibitors, direct and indirect Factor Xa inhibitors (oral and intravenous), and modulators of the protein C pathway. However, with all of these agents, it is not yet clear whether the new target and/or ease of use can overcome noted side effects including toxicity, bleeding, and contact system activation (See Chapters 10 and 11 for further discussion).[339]

Continued studies will refine the implementation of current therapy; target therapy given selectively to high-risk patients and to those likely to respond (pharmacogenomics); and study the incremental benefits and safety of various antiplatelet combinations and their interactions with other medications.[251] Continuing advances in understanding the mechanisms of thrombosis, as well as the development of new techniques for studying its regulation, have led to an enhanced understanding of thrombotic disease as well as to the availability of new classes of antithrombotic drugs.

Acknowledgment

Some of the material contained in this chapter was contributed previously by Professor Lionel Opie in the second edition of this textbook. The editor and the authors of this chapter wish to acknowledge the continued pivotal contributions of Professor Opie to our understanding of cardiovascular pharmacotherapeutics.

Chapter 6

Mechanical Approaches to Percutaneous Coronary Intervention

Juhana Karha, A. Michael Lincoff, and Stephen G. Ellis

CHAPTER CONTENTS

Interventional cardiology, the application of catheter-based techniques to the treatment of coronary artery, valvular, or congenital cardiac diseases, arose as the culmination of the use of catheters as instruments for the *diagnosis* of heart disease. Cournand[1] and others first reported on the potential utility of the right heart catheter in 1941, leading ultimately to the development in the late 1950s and 1960s of selective coronary arteriography by Sones and Judkins. Dotter and Judkins introduced the therapeutic application of percutaneous angioplasty of atherosclerotic peripheral vascular stenoses in 1964 with a cumbersome system of multiple coaxial catheters.[2] The modern era of cardiovascular intervention began with the development by Andreas Gruentzig of a balloon catheter, with which the first percutaneous transluminal coronary angioplasty (PTCA) procedure was performed in 1977 in Zurich.

Since the 1970s, there has been explosive growth in the field of interventional cardiology. Although this technique was initially restricted to relatively young patients with stable angina, normal left ventricular function, and simple stenoses of a single coronary artery, current indications have expanded to include unstable angina and acute myocardial infarction, elderly patients and those with depressed left ventricular function, multivessel coronary artery disease, and stenoses with complex morphology or in coronary artery bypass grafts. A variety of devices for coronary intervention have been advocated to overcome some of the limitations of balloon angioplasty in treating lesions with high-risk characteristics or reversing the complications of balloon dilation. Stents were developed and shown to reduce the incidence of vessel closure and restenosis after balloon angioplasty. To further address the problems of in-stent restenosis, drug-eluting stents (stents coated with anti-proliferative medications) were designed. Imaging techniques including intravascular ultrasound and Doppler flow assessment provide information regarding plaque morphology and physiological function which are complementary to data derived from conventional contrast angiography, facilitating the selection of optimal means of revascularization and assessment of outcome.

CORONARY ANGIOPLASTY

Since the introduction of coronary balloon angioplasty into clinical practice in 1977,[3] improvements in equipment design and operator experience have permitted this procedure to be applied to the treatment of a broad spectrum of coronary artery disease. The development of new devices for percutaneous coronary revascularization was motivated by the recognition that, despite improvements in equipment design and operator experience, balloon angioplasty remained substantially limited by the risk of procedural complications, by difficulties in achieving an adequate angiographic result, and, most importantly, by the persistently high incidence of restenosis. Stenoses that are complex, calcified, long, bulky, eccentric, totally occluded, within saphenous vein grafts, or that are associated with thrombus are particularly challenging to treat with conventional methods of balloon dilation. The potential efficacy of new devices relative to PTCA appears to be twofold. First, the mechanical support of the arterial wall afforded by stents reduces acute ischemic complications caused by vascular disruption and later restenosis caused by recoil and remodeling. Second, in certain high-risk lesion subsets, other devices can achieve a better angiographic result—for instance, by actual removal of plaque.

Equipment

Guide catheters of diameters ranging from 5 to 9 Fr provide atraumatic coronary ostial engagement and support for passage of dilation catheters with profiles of 0.9 mm (distal external diameter). Steerable guidewires, with diameters of only 0.009 to 0.018 inches and tips of varying degrees of stiffness, can be precisely shaped allowing even distal coronary lesions beyond tortuosity to be routinely accessed. Current balloon angioplasty catheters have deflated profiles of 1 mm or less and shaft constructions that optimize trackability and transmission of "push" force. Different polymers are employed as balloon materials, permitting accurate sizing, conformability to angulated lesions, and dilation of rigid lesions with pressures of greater than 20 atmospheres. There have been substantial concomitant improvements in the quality of radiographic imaging in the cardiac catheterization laboratory. The development of high-resolution fluoroscopy, digital image reconstruction, and on-line computerized quantitative analysis permits clear visualization of small diameter guidewires and catheters within the vasculature, the use of high-definition frozen frames as coronary "road maps," accurate assessment of luminal dimensions before and after

revascularization, and improved detection of vascular wall dissection or thrombus formation.

A stent is a metal prosthetic device that is permanently implanted within a diseased blood vessel to provide a scaffold for disruptions of the vascular wall and prevent elastic recoil and remodeling. Stent designs may be mesh structure, coil, slotted tube, or ring shapes. A substantial body of observational data supports the efficacy of stents as a means of reversing acute mechanical complications of balloon angioplasty and achieving an improved immediate angiographic result. More importantly, randomized clinical trials have shown that these devices reduce the incidence of angiographic restenosis and the need for repeat revascularization procedures compared with balloon angioplasty. Accordingly, stents represent the most important nonpharmacologic advance in the field of interventional cardiology since the introduction of balloon angioplasty and are used in the majority of percutaneous revascularization procedures worldwide.

Currently, more than 50 different types of stents are in clinical use or under investigation. Stents have also been developed for specialized applications, such as the treatment of bifurcations, ostial lesions, or aneurysms or perforations. Most stents are balloon expandable, crimped by the manufacturer in a collapsed form on a deflated angioplasty balloon and deployed at the coronary stenosis by balloon inflation. Self-expanding designs use specialized delivery catheters, with deployment of the stent by withdrawal of a constraining sheath.

Drug-eluting stents are coated with medications that are released into the bloodstream and the surrounding vessel wall. A polymer matrix serves as an interface between the stent and the medication. This method of local drug delivery provides the advantage of minimizing side effects of the pharmacological agent because systemic concentrations remain low. In contrast to catheter-based local delivery strategies, the stent-mediated delivery allows for more continuous release over an extended period of time. Multiple variables affect the process of drug elution: the stent design, the coating matrix, the drug itself, and the vessel wall. Ideally, stents with larger surface areas, smaller gaps between cells, and less postdeployment deformation would enhance the process of drug delivery. The drug-eluting stents in current clinical use are conventional stent models and were not designed for maximizing drug delivery. Ideally, the coating matrix, which modulates the kinetics of drug elution, would be biologically inert and durable. Durability is important because any degradation of the polymer that serves as the coating matrix may cause local inflammation and thereby accelerate the process of in-stent restenosis. The sirolimus- and paclitaxel-eluting stents in current clinical practice employ a synthetic polymer as a coating matrix. The sirolimus-eluting Cypher stent is coated with a mixture of two polymers in a 2:1 ratio, polyethylene-co-vinyl acetate and poly *n*-butyl methacrylate. These polymers are coated onto a stainless steel BX Velocity stent. The polymer in the paclitaxel-eluting Taxus stent is a poly (styrene-b-isobutylene-b-styrene) and is mounted on an Express stainless steel stent. Desirable properties of the medication itself are antiproliferative efficacy and homogeneous diffusion. Drug kinetics may also be affected by the size of the molecule, the hydrophobicity, and the extent of protein binding. In both the Cypher and Taxus stents, most of the drug release into the vessel wall occurs during the first month.

Technique

Patients receive antiplatelet and antithrombin therapy, and arterial access is via percutaneous femoral, brachial, or radial puncture. At some institutions, a pulmonary artery catheter is placed for monitoring of right heart pressures for high-risk patients. The coronary ostium is engaged with a suitable guide catheter, and a steerable coronary guidewire is manipulated under fluoroscopic guidance across the stenosis. A majority of procedures involve stent implantation. In cases of suitable anatomy, direct stenting without predilation may be performed. In these cases, the balloon catheter with the stent preloaded on the outer surface of the balloon is advanced across the guidewire to the lesion and inflated to a pressure at which the stent is fully expanded (typically at 12 to 16 atmospheres). An inadequate result may require balloon postdilation. Many lesions require balloon dilation before a stent placement is possible (predilation). The predilation ensures that a stent can be passed through the stenosis and that it can be completely expanded. Following attempted predilation, inadequate improvement in the degree of stenosis may be treated by repeat balloon inflations, exchange for a balloon catheter of larger inflated diameter, or debulking by an atherectomy device. A minority of stenoses are not suitable for stenting after balloon angioplasty. These lesions are typically in small or tortuous vessels, or in side branches where an ostial stent could compromise the main vessel. In-stent restenosis lesions are best treated by placement of a drug-eluting stent within the prior stent. In most laboratories, intravascular ultrasound imaging is not routinely used after stent placement but may be used in select cases to detect lesion characteristics, such as calcification or dissection, or to confirm the adequacy of stent expansion.

After the angioplasty procedure, patients are generally observed overnight in an inpatient cardiology unit for the infrequent development of recurrent myocardial ischemia or hemorrhagic complications. Postprocedural ischemia, particularly if prolonged and associated with electrocardiographic changes, usually necessitates urgent repeat angiography and revascularization. Routine long-term follow-up is not uniform but should include risk factor modification and surveillance for recurrent ischemia. Functional testing after routine percutaneous coronary intervention (PCI) was not associated with clinical benefit in the Routine versus Selective Exercise Treadmill Testing after Angioplasty (ROSETTA) registry.[4]

Pharmacotherapy

The two major targets of adjunctive pharmacotherapy before, during, and after PCI are the platelet and the coagulation cascade. The benefits of the antiplatelet and antithrombin medications need to be weighed against their increased bleeding risks. All patients receive aspirin before PCI and then indefinitely after the procedure. For long-term therapy, the daily dose of 81 mg appears to provide the optimal balance between efficacy and safety. Patients with documented aspirin allergy receive clopidogrel instead. Because a majority of angioplasty procedures now include stenting, patients receive a loading dose of clopidogrel followed by at least 4 weeks of therapy (at a daily dose of 75 mg). In cases of balloon angioplasty without stenting, it is unclear if a thienopyridine adds benefit beyond that of aspirin alone. Patients with clopidogrel

allergy receive ticlopidine instead. Ideally, the loading dose should be administered at least 2 hours before the PCI,[5] but this is not always feasible. The optimal loading dose is not known. Some reports and one small randomized trial suggest that a 600 mg loading dose may be superior to 300 mg for suppression of ischemic events without an increased risk of bleeding.[6] The goal of the loading dose is to rapidly achieve therapeutic levels of inhibition of platelet aggregation (IPA). More investigation is required to define the optimal (from both efficacy and safety perspectives) level of IPA to support PCI.

The optimal duration of dual antiplatelet therapy (aspirin + clopidogrel) after PCI is unknown. The Clopidogrel for the Reduction of Events During Observation (CREDO) trial demonstrated in patients undergoing PCI (with bare metal stenting) that clopidogrel use beyond the traditional 1 month and through 1 year was associated with further clinical benefit.[7] These findings were consistent with the clinical benefit of long-term clopidogrel therapy observed in the PCI-Clopidogrel in Unstable angina to prevent Recurrent Events (CURE) study, which also predated the era of drug-eluting stenting.[8] Based on these findings, many operators continue dual antiplatelet therapy for 1 year in patients who have undergone PCI with a bare metal stent and who are not at an increased bleeding risk. Multiple case reports have described the occurrence of a stent thrombosis years after drug-eluting stent (DES) placement and shortly after the discontinuation of clopidogrel.[9] These reports raise the possibility that it may be beneficial to continue clopidogrel therapy for patients with a DES even years after its placement. More information is required, however, before any recommendations can be made about this issue.

The platelet glycoprotein (GP) IIb/IIIa receptor antagonists provide platelet inhibition beyond that achieved with aspirin and clopidogrel. A sizable body of evidence demonstrates that abciximab, the first of these compounds, reduces periprocedural ischemic events and likely reduces long-term mortality following PCI.[9] Treatment with eptifibatide has also been associated with reduced periprocedural ischemic events.[10] The combination of GP IIb/IIIa blockade with low-dose weight-adjusted heparin thus became the standard therapy for suppression of ischemic complications after PCI, albeit at a somewhat increased risk for bleeding complications. However, a randomized trial failed to demonstrate incremental benefit of abciximab among patients undergoing stenting with a regimen of high-dose heparin and pretreatment (of at least 2 hours) with 600 mg of clopidogrel, although high-risk patients were excluded from this study.[11,12] More importantly, a large-scale study using the direct thrombin inhibitor bivalirudin (see later) instead of heparin demonstrated that similar ischemic outcomes with less bleeding could be achieved using GP IIb/IIIa blockade only in a provisional, rather than planned, fashion[13] in elective or urgent PCI. Administration of abciximab during PCI for acute coronary syndromes (or perhaps for an angiographically visible thrombus) remains the standard of care.

During coronary angioplasty, the advancement of guidewires, balloon catheters, and other devices into the coronary arteries requires anticoagulation to prevent iatrogenic thrombosis. This has traditionally been achieved with intravenous unfractionated heparin with the target activated clotting time of >250 to 300 seconds. However, some operators use the low-molecular-weight heparin enoxaparin as adjunctive anticoagulation in PCI. Bivalirudin, a direct thrombin inhibitor, has been introduced into contemporary interventional practice by the findings of the Randomized Evaluation in PCI Linking Angiomax to Reduced Clinical Events (REPLACE)-2 trial of 6010 patients undergoing elective or urgent PCI.[13] This study established that a strategy of bivalirudin with provisional GP IIb/IIIa (that is, used in the event of a procedural complication) was not inferior to unfractionated heparin plus planned GP IIb/IIIa inhibitor use with respect to ischemic outcomes, and superior in terms of bleeding complications.

Pathophysiology

The mechanisms by which coronary angioplasty may improve vessel luminal dimensions have been characterized by studies in animal models and human cadaveric specimens and by intravascular ultrasound imaging. The radial force exerted by balloon dilation within a coronary artery universally produces endothelial denudation with variable degrees of fracture and separation of plaque from the underlying media, stretching of the medial and adventitial layers, and fracture or dissection of the media. On the basis of these findings, Waller[14] has postulated five different mechanisms for the hemodynamic benefit derived from balloon angioplasty; for any particular lesion one or more of these mechanisms may be operative. *Plaque compression* appears to play only a minor role in the improvement of the dense fibrocalcific stenoses typically present in advanced coronary artery disease. A major mechanism of balloon angioplasty appears to be *plaque fracture*, with immediate formation of fissures within the atherosclerotic lesion that provide channels for blood flow; the ultimate luminal geometry and extent of enlargement are influenced by subsequent plaque healing and remodeling. Additional expansion in the cross-sectional area is obtained when more extensive arterial injury results in localized *medial dissection*. *Stretching* may also occur, providing an immediate improvement of luminal diameter, which may be partially or completely attenuated, however, by elastic recoil. Similarly, vessels in which an eccentric plaque is dilated may be enlarged simply as a result of *stretching of plaque-free arterial segments* with little or no fracture or compression of plaque; early loss of luminal dimensions is due to gradual relaxation of the overstretched segment.

With the deployment of stents, additional pathophysiological considerations arise. In animal models, three somewhat distinct phases in the vascular response to stent implantation may be appreciated by serial observations.[15,16] The thrombotic phase, occurring within the first hours to days, is characterized by formation of extensive platelet- and fibrin-rich thrombus over and surrounding the stent struts. This is followed by a cellular recruitment phase, occurring 3 to 9 days after injury, marked by re-endothelialization and infiltration of the thrombus by monocytes and lymphocytes from the luminal surface outward. These cells secrete growth factors that stimulate smooth muscle cell migration and proliferation. In the final proliferative phase, colonization of the thrombus and resorption of fibrin by smooth muscle cells occur, eventually replacing the thrombus with a neointimal mass. A limited number of stents subsequently retrieved from patients undergoing coronary artery bypass surgery showed deposition of platelets, fibrin, and leukocytes during the first

3 to 7 days following implantation, with subsequent ingrowth of varying degrees of neointima by 3 to 10 months.[17,18] Another important consideration with stenting is possible axial displacement of plaque at the proximal and distal edges. This may occur either immediately or manifest later as restenosis.

Outcome

By the end of the 1980s, the procedural success rate with balloon angioplasty had reached more than 90% in highly selected patients.[19,20] The majority of patients treated with coronary angioplasty experience substantial immediate relief of symptoms of myocardial ischemia. The procedure has been estimated to be effective in decreasing or eliminating angina in 88% and 76%, respectively, of patients,[21] with improvement or resolution of ischemic signs on exercise stress testing.[22] The extent of improvement in symptom status is better among patients with single-vessel coronary artery disease than among those with multivessel involvement.[23,24] Major ischemic complications occur infrequently during coronary angioplasty. With the greater use of stents in the 1990s, the incidence of emergency bypass surgery fell to 0.3%.

Among patients who have undergone initially successful percutaneous revascularization, outcome over the first 6 to 12 months is influenced primarily by the development of recurrent stenoses at treated sites (*restenosis*), whereas events over the longer term appear dependent on progression of atherosclerotic disease. Recurrence of ischemic signs or symptoms among patients treated with coronary angioplasty appears to occur primarily over the first year after the procedure.

Abrupt Vessel Closure

An important determinant of ischemic complications associated with coronary angioplasty is the occurrence of *abrupt vessel closure*, the sudden occlusion of the target or adjacent segment of a coronary vessel during or after percutaneous revascularization. The reported incidence of abrupt closure with balloon angioplasty has ranged from 4.2% to 8.3%.[25-28] Although relatively infrequent, abrupt vessel closure has important clinical sequelae: rates of death, myocardial infarction, and emergency bypass surgery have been reported to range as high as 8%, 54%, and 72%, respectively.[29] Long-term ischemic event rates have also been shown to be elevated among patients who have suffered even transient abrupt closure.[30]

The pathophysiological mechanisms of abrupt coronary occlusion are similar to those that produce the therapeutic benefit derived from balloon dilation. Although plaque and medial fissuring induced by balloon angioplasty usually remain localized, extensive disruption of the medial layer can occur, leading to obstructive dissection flaps or intramural hematoma. Exposure of subendothelial vascular wall components results in platelet deposition and activation with formation of thrombin; occlusive thrombosis may occur, often in association with blood stasis produced by medial dissection flaps. In some patients, particularly those with unstable ischemic syndromes, propagation of preexistent mural thrombus at the treatment site may be the predominant mechanism of coronary obstruction.

A number of preventive measures may limit the occurrence of abrupt vessel closure during PCI. Pharmacological approaches focus on suppression of platelet aggregation and thrombus formation at the site of balloon dilation or on pre-procedural resolution of pre-existent mural thrombus. Procedural mechanical factors that may reduce the risk of abrupt closure include selection of appropriately sized balloons to avoid excessive overdilation relative to the normal coronary diameter,[31,32] the use of long (30 to 40 mm) balloons for angulated or diffuse lesions, or prolonged inflations,[33,34] and stent placement.

If abrupt closure occurs, stent implantation is usually successful in this setting, by virtue of its "scaffolding" effect at the disrupted angioplasty site; other ablative devices have also been occasionally employed. Administration of platelet GP IIb/IIIa antagonists may be particularly effective in patients with thrombotic coronary occlusion.[35] The preponderance of published data, however, suggests that fibrinolytic agents such as urokinase are of limited or no usefulness.[27,28,36] When emergency surgical revascularization is required, perioperative death and myocardial infarction occur more frequently than would be expected for comparable patients managed by primary elective surgery, with published mortality rates ranging from 1.4% to 19% and perioperative Q-wave infarction rates from 20% to 57%.[37]

The most effective means to prevent acute vessel closure is to use a stent in a planned fashion. However, when PTCA is performed *without planned* stent placement, bailout or unplanned stent placement for abrupt or threatened coronary closure is a highly effective means of improving procedural outcome and reducing the risk of ischemic complications. By virtue of their ability to "tack down" obstructive dissection flaps, minimize contact between blood and thrombogenic subintimal arterial wall components, limit elastic recoil or spasm, and optimize blood flow dynamics, stents produce excellent angiographic resolution of acute coronary occlusion or major dissection. Despite some early concerns, with contemporary techniques of deployment and antithrombotic therapy, stenting can be expected to reverse abrupt vessel closure in a large proportion of cases with low rates of ischemic complications.

Restenosis

The principal factor limiting the long-term benefit of PCI (with or without stenting) is restenosis, the angiographic renarrowing of the vessel lumen following successful balloon dilation of a vascular lesion. The reported incidence of restenosis (before the era of drug-eluting stents) ranged from 30% to 50%, depending on the method of follow-up and the criteria used to define restenosis. The most common clinical manifestation of restenosis is recurrence of anginal chest pain.[31,38] Myocardial infarction as the first indication of restenosis is rare, and it has been speculated that the fibroproliferative restenotic lesion is less likely than the lipid-laden native atherosclerotic plaque to undergo plaque rupture.[39] The presence of angiographic restenosis has only limited predictive value for the occurrence of clinical events—with up to 30% of patients with restenosis found to be asymptomatic.[38,40,41] The apparent discordance between clinical outcome and angiographic restenosis is probably related to the influence of collateral vessels,[40] incomplete revascularization, or progression of atherosclerotic disease in other arteries, as well as to the limitations of a dichotomous definition of

restenosis. Moreover, estimation of the true *functional* severity of stenoses by angiography may be problematic, as has been suggested by intravascular ultrasound and Doppler flow studies. Repeat revascularization of patients with angiographic restenosis is generally reserved for those with clinical symptoms or demonstrable ischemia because the prognosis in asymptomatic patients is quite favorable.[40,42]

The pathogenesis of restenosis is complex and multifactorial. Restenosis within lesions that do not show evidence of intimal hyperplasia may result, in part, from stretching of atherosclerotic plaque or of disease-free arterial wall (in eccentric lesions) during balloon dilation, followed by elastic recoil.[43] More importantly, however, chronic shrinkage or "remodeling" of the arterial cross-sectional area has been shown to occur after balloon dilation, with pathological findings in animal models demonstrating structural changes extending throughout the arterial wall.[44,45] Serial intravascular ultrasound studies in humans also support the concept that remodeling is an important mechanism of restenosis after balloon angioplasty.[46]

Another major mechanism of restenosis is intimal fibrous hyperplasia. The magnitude of this response, and hence the amount of proliferative tissue, appear to be proportional to the degree of arterial injury during percutaneous revascularization.[47,48] The cascade of events leading to the formation of the neointimal proliferative lesion seems to be initiated by endothelial denudation, plaque disruption, and exposure of subendothelial components, leading to platelet deposition and thrombus formation. Growth and chemotactic factors released from platelets, inflammatory cells, endothelium, and smooth muscle cells induce proliferation and migration of vascular smooth muscle cells from the arterial media to intima, synthesis of extracellular collagen and proteoglycan matrix, and excessive fibrocellular accumulation.[47,49-52] The mechanisms by which stents reduce the incidence of restenosis appear to be by improvement in the immediate angiographic result (better acute gain in luminal diameter), as well as by prevention of early elastic recoil and chronic negative remodeling. Restenosis within a stent occurs exclusively by neointimal hyperplasia and ingrowth between stent struts,[53,54] a process that is not diminished, and is, in fact, increased by stenting relative to balloon angioplasty.[55] Luminal diameter within a stent typically decreases over 6 months after implantation due to neointimal hyperplasia, with evidence of modest regression of stenosis thereafter over 3 years of follow-up.[56]

Sirolimus and paclitaxel are the bioactive compounds of the two drug-eluting stents in current clinical use (Fig. 6–1). Sirolimus is a macrolide antibiotic with both immunosuppressive and antimitotic activities. It binds FK binding protein in the vessel wall smooth muscle cell cytosol, and that complex then binds the mammalian target of rapamycin (mTOR)—inhibiting its activation and ultimately leading to arrest of cell cycle in the G_1 phase. This process corresponds to inhibition of smooth muscle cell growth, retarding the process of neointimal proliferation and in-stent restenosis. Paclitaxel, a lipophilic molecule derived from the Pacific yew tree *Taxus brevifolia,* acts via stabilizing microtubules and has known anti-tumor action (it is the active ingredient in the widely used chemotherapy drug Taxol). It shifts the cytoskeletal equilibrium toward decreased cell proliferation. Retrospective studies have identified several clinical, lesion morphological, and procedural factors that may influence the risk of restenosis following PCI, although the associations among many of these features and restenosis have been variable. Among the clinical factors, only the presence of unstable angina,[57-60] variant angina,[61] and diabetes mellitus[38,58,59] have consistently predicted an elevated incidence of restenosis. Factors associated with an increased risk of in-stent restenosis include stenting of restenotic or saphenous vein graft lesions or total occlusions, lesion length, multiple stents, greater residual stenosis, diabetes mellitus, and smaller reference vessel diameter.[62] Rates of restenosis and target vessel revascularization after stenting of these higher risk lesions have been shown to be 2 to 4 times greater than with stenoses that meet the restricted criteria of the original Benestent and STRESS trials.[63] To date, the factors that have been associated with in-stent restenosis in the drug-eluting stent era are diabetes mellitus, small vessel size, and lesion length.[64]

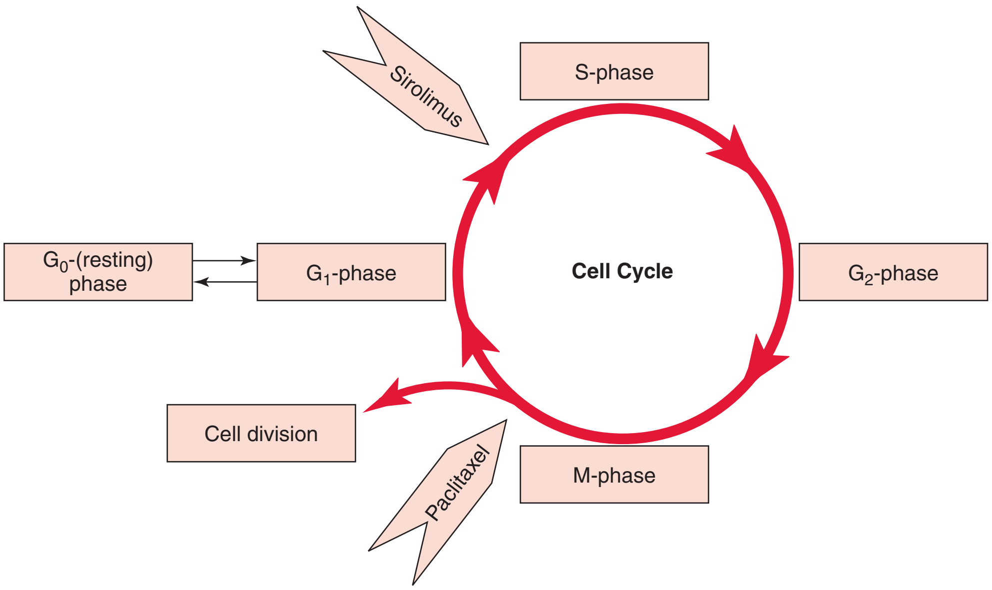

Figure 6–1 Sirolimus and paclitaxel inhibit the cell cycle during the G_1- and M-phases, respectively.

Notwithstanding the efficacy of stenting to prevent or treat abrupt closure, the widespread clinical application of this technology has been motivated primarily by the impact of stents on the incidence of restenosis. Two seminal randomized trials compared placement of the Palmaz-Schatz stent with conventional balloon angioplasty in a highly select group of patients with de novo native coronary stenoses, providing the first compelling evidence that these devices can reduce the frequency of repeat revascularization procedures and angiographic restenosis.[65,66] Subsequent studies confirmed these findings among patients with a broader spectrum of clinical syndromes and coronary lesion morphologies, including those with chronic total occlusions, restenotic lesions, and saphenous vein graft stenoses.[67-73] Over long-term follow-up (6 to 12 months) in these trials, rates of ischemic events were reduced by 34% to 76% by stenting compared with balloon angioplasty, coupled with 20% to 57% reductions in angiographic indices of restenosis. Importantly, long-term clinical benefit observed in these studies was confined to reductions in the need for repeat target vessel revascularization procedures or recurrent ischemia, and no trial has shown a convincing suppression by stents of the long-term risk of death or myocardial infarction. These findings of randomized stent trials have been confirmed by observational reports of clinical practice. A database analysis of 9594 percutaneous interventional procedures performed in British Columbia, Canada, between 1994 and 1997 showed a significant decrease in the rate of adverse cardiac events by 1 year, due exclusively to a reduction in the incidence of repeat target vessel revascularization (24.4% to 17.0%, $P < 0.001$), concordant with a rise in the rate of stent use from 14% to 59% over the same time period.[74]

Although the ingrowth of neointima is usually responsive to repeat balloon dilation within the stent, rates of recurrence are high. In the U.S. Palmaz-Schatz registry, recurrence of stenosis was observed in 54% of patients treated for in-stent restenosis.[75] The risk of recurrent restenosis appears to be related to the pattern of in-stent luminal narrowing, ranging from 10% to 31% with focal narrowings to as high as 63% to 88% with diffuse in-stent restenosis.[76,77] A large number of pharmacological agents have been tested that might be expected to influence favorably different components of the arterial response to injury,[78] but clinical trials have almost uniformly failed to demonstrate an unequivocal reduction in the incidence of restenosis with systemic pharmacological therapies. The treatment of choice for in-stent restenosis is repeat PCI with placement of one or more drug-eluting stents within the stenosed stent. Kastrati and colleagues demonstrated in the 300-patient Intracoronary Stenting and Angiographic Results—Drug-Eluting Stents for In-stent Restenosis (ISAR-DESIRE) randomized trial that patients whose in-stent restenosis was treated with a drug-eluting stent had a lower rate of angiographic restenosis and a lower need for subsequent target vessel revascularization compared with patients treated with a bare metal stent.[79] The rate of angiographic restenosis of ≥50% 6 months after the PCI was 14.3% and 21.7% among patients treated with sirolimus- and paclitaxel-eluting stents, respectively, and 44.6% among patients in the bare metal stent group ($P \leq 0.001$ for both comparisons of drug-eluting stent with bare metal stent).

Drug-Eluting Stents and Restenosis

The emergence of drug-eluting stents (DES) has been a major advance in the struggle against in-stent restenosis. Both sirolimus- and paclitaxel-eluting stents have been shown to reduce the incidence of angiographic and clinical measures of restenosis. The first-in-man study of the sirolimus-eluting stent (SES) demonstrated that, in 45 patients with angina pectoris and native coronary artery lesions, angioplasty with SES was safe with no cases of in-stent restenosis at 24 months.[80] These encouraging findings set the stage for the first randomized trial comparing SES with the identical BX Velocity stent without the coating (thus referred to as *bare*) among 238 patients with simple angiographic stenoses (Table 6–1). The RAndomized study with the sirolimus-eluting BX VELocity balloon-expandable stent (RAVEL) demonstrated a remarkable zero percent incidence of binary restenosis (defined as 50% stenosis) and no loss of luminal area at 6 months after stenting among a very low-risk group of patients treated with the SES, compared with a 26.6% restenosis rate and a mean 0.80 mm late loss of luminal dimension in the control group.

In concert with the angiographic findings, the sirolimus stent group also had a lower rate of target vessel revascularization (TVR) at up to 12 months of follow-up compared

Table 6–1 Clinical and Angiographic Outcomes in Bare Metal Stent versus Drug-Eluting Stent Randomized Trials

with the bare metal stent (BMS) group (0% versus 23.7%, $P < 0.001$).[81] The SIRolImUS-coated BX Velocity stent in the treatment of patients with de novo coronary artery lesions (SIRIUS) trial confirmed the results of the RAVEL trial in a larger study with broader inclusion criteria.[82] The patients ($n = 1058$) were randomized to receive a sirolimus-eluting stent versus a bare metal stent, with the primary endpoint a combination of death, myocardial infarction, or TVR within 9 months. The sirolimus group had a lower incidence of primary endpoint, driven by the reduced need for TVR (4.1% versus 16.6%, $P < 0.001$). The E-SIRIUS trial ($n = 352$) extended these findings to patients with longer lesions in smaller vessels.[83] Treatment with sirolimus-eluting stent was associated with less binary in-stent restenosis (5.9% versus 42.3%, $P = 0.0001$) and less target lesion revascularization (4.0% versus 20.9%, $P < 0.0001$) at 8 months compared with bare metal stenting. Similar results were noted in the C-SIRIUS trial.[84] The benefit of the sirolimus-eluting stent use has also been demonstrated in a real-world registry. The Rapamycin Eluting Stent Evaluated At Rotterdam Cardiology Hospital (RESEARCH) registry compared consecutive patients ($n = 508$) who received sirolimus-eluting stents with those who had been treated with bare metal stents ($n = 450$) prior to the availability of SES.[85] Although the SES group was at higher risk for ischemic outcomes than the BMS group, based on clinical and angiographic characteristics, the rate of clinically driven target vessel revascularization at one year was much lower in the SES group (3.7% versus 10.9%, $P<0.001$).

Paclitaxel-eluting stents (PES) have also demonstrated clinical benefit in randomized trials. The TAXUS I trial evaluated slow-release TAXUS NIRx stent versus bare NIR stent in 61 patients with simple coronary lesions.[86] The angiographic measures of restenosis were reduced in the TAXUS stent group. In the TAXUS II trial, 536 patients were randomized to TAXUS stent versus an identical bare metal stent that served as the control.[87] Angiographic and intravascular ultrasound indices of restenosis, as well as the rate of target lesion revascularization, were reduced in the TAXUS stent groups compared with the control groups. The largest PES trial to date, the TAXUS IV trial, randomized 1314 patients undergoing PCI with stenting of a single, previously untreated native coronary artery lesion to slow-release TAXUS EXPRESS stent versus bare EXPRESS stent.[88] The rate of ischemia-driven TVR at 9 months was lower in the PES group compared with the BMS group (4.7% versus 12.0%, $P < 0.001$) and the angiographic endpoints characterizing in-stent restenosis were similarly reduced in the PES group.

The TAXUS V trial included patients with long coronary lesions (up to 46 mm) and lesions in small vessels (down to a diameter of 2.25 mm).[89] This 1172-patient trial reported a lower rate of major adverse cardiac events (death, myocardial infarction, or target vessel revascularization) at 9 months in the TAXUS group compared with the bare metal stent group: 15.0% versus 21.2%, $P = 0.008$). This was driven by a lower rate of target *lesion* revascularization in the TAXUS group (8.6% versus 15.7%, $P < 0.001$).

The TAXUS VI trial used the moderate-release formulation paclitaxel-eluting stent and studied 448 patients with long lesions (up to 40 mm). The primary endpoint of the study, the rate of target vessel revascularization at 9 months, was lower in the TAXUS stent group compared with the BMS group: 9.1% versus 19.4%, respectively, $P = 0.003$. Of note, this rate in the overlapping stent subgroup was reduced from 24.6% in the control group to 1.6% in the TAXUS stent group ($P < 0.0001$). In summary, the TAXUS V and VI trials have extended the benefits of the paclitaxel-eluting stent to a group of patients with more complex coronary lesions.

The sirolimus- and paclitaxel-eluting stents have been compared in several clinical trials (Table 6–2). In the REALITY trial, the angiographic endpoint of late loss favored SES compared with PES.[90] The SIRTAX trial demonstrated lower rates of late loss, restenosis, and TLR with SES.[91] Similarly, the ISAR-Diabetes trial revealed a lower rate of late loss and restenosis among diabetics treated with SES.[92] The ISAR-DESIRE trial evaluated patients with in-stent restenosis (with prior bare metal stent).[79] The rate of target vessel revascularization at 6 months after PCI was lower in the SES group compared with the PES group, but there was no statistically significant difference in the rate of restenosis. Kastrati and colleagues recently published a meta-analysis of six randomized trials[79,90-94] comparing the sirolimus-eluting stent with the paclitaxel-eluting stent.[95] The incidence of target lesion revascularization was less frequent among patients randomized to SES compared with PES (5.1% versus 7.8%, odds ratio 0.64, $P = 0.001$). Likewise, angiographic restenosis was less frequent with SES versus PES (9.3% versus 13.1%, odds ratio 0.68, $P = 0.001$). These early comparative studies between SES and PES show that there is less late loss with SES, although the impact on clinical revascularization rates varies. The emerging consensus is that, in cases of high-risk lesions, late loss is a significant issue and SES implantation is recommended (Fig. 6–2).

OTHER DEVICES

Devices that remove atheromatous material are used as adjuncts in coronary angioplasty. The directional atherectomy

catheter cuts the stenosis using a spinning blade, while rotational atherectomy abrades and pulverizes the plaque. Distal embolic protection devices are positioned downstream of the site of angioplasty and collect embolizing plaque material before it reaches the myocardial microvasculature. Transluminal extraction atherectomy, cutting balloon, rheolytic thrombectomy, and excimer laser are used less commonly in the current practice. Intracoronary irradiation (brachytherapy), a common treatment for in-stent restenosis in the past, is now infrequently used with the emergence of drug-eluting stents (Fig. 6–3).

Atherectomy

The directional coronary atherectomy catheter consists of a metal cylinder at its distal end which houses a coaxial rotating cup-shaped blade. After multiple atherectomy cuts, most patients require adjunctive balloon angioplasty and stenting to achieve an optimal angiographic result. Plaque removal by directional atherectomy may produce an angiographic result that is superior to that obtainable by PTCA, particularly for lesions that are eccentric, ostial, restenotic, or associated with intraluminal thrombus.[96,97] Failures of atherectomy are most frequently due to inability to pass the bulky catheter to or across the coronary stenosis, although other complications include coronary occlusion, embolization, or perforation. Directional atherectomy is time-consuming and technically demanding, and a substantial operator learning curve exists. In contrast, stenting does not require large vascular access sheaths, and it can be conducted quickly and relatively easily. Directional atherectomy may be best suited for certain lesion subsets less amenable to stenting, such as bifurcation lesions, ostial stenoses, or in-stent restenosis.

The rotational atherectomy catheter uses a rapidly spinning abrasive tip welded to the end of a flexible metal drive shaft to grind the internal lumen of an atherosclerotic plaque. The distal end of the catheter consists of an elliptical metal burr coated with diamond chips that rotates while it is slowly advanced across the atherosclerotic plaque. Rotational atherectomy theoretically operates on the principle of differential cutting, whereby rigid material such as calcium or fibrotic plaque is preferentially pulverized rather than the elastic components of the arterial wall.[98] As such, this technique has been particularly advocated for heavily calcified, inelastic or "nondilatable," eccentric, and diffuse coronary lesions. Complications of rotational atherectomy include "slow flow" reflecting distal embolization as well as coronary dissection and perforation. The clinical indication for rotational atherectomy is, therefore, to improve acute procedural success rates in certain coronary lesion subsets that are poorly suited for balloon angioplasty, including heavily calcified vessels, rigid nondilatable stenoses, aortic or branch ostial lesions, and bifurcation stenoses.

Embolic Protection Devices

Downstream embolization of atherosclerotic debris is inevitable to some extent during angioplasty. Such embolization results in increased no-reflow phenomenon, post-procedural myonecrosis, and microvascular dysfunction, all of which are associated with poorer long-term outcome. Much interest has recently focused on mechanical solutions for this challenging problem. The various embolic protection devices (EPD) are positioned distally to the site of angioplasty with the goal of collecting the debris before it reaches the microvasculature. After the procedure, the EPD is removed along with the material that has been intercepted. The two main design types of the various EPDs, either in commercial use or in development, are filters and occlusion balloons. The filter-based systems are nonocclusive and preserve blood flow through small pores (~100 μm). The balloon-occlusion based systems temporarily occlude the distal vessel followed by aspiration of liberated atheromatous and thrombotic material. The challenges with the use of EPD include deliverability of the device in cases of severe stenosis or tortuosity, absence of a suitable distal deployment or "landing" zone, the presence of any side branches between the lesion and the device (that might receive the debris before it reaches the EPD), initial embolization with the manipulation of the wire before the placement of the EPD, and imperfect collection

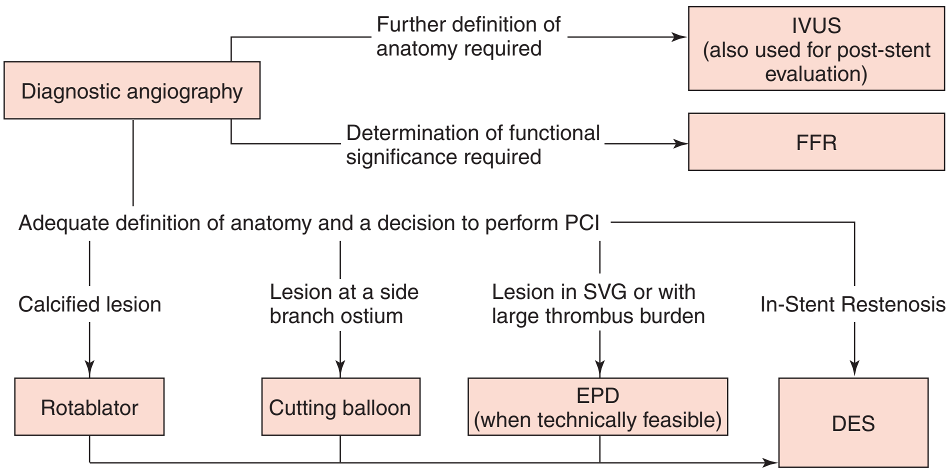

Figure 6–3 Following diagnostic angiography, intravascular ultrasound (IVUS) and pressure wire may be used to obtain further information. Specific lesion characteristics call for the use of rotational atherectomy (abbreviated as "rotablator"), cutting balloon, and distal embolic protection devices (EPD). DES, drug-eluting stent; FFR, fractional flow reserve; PCI, percutaneous coronary intervention; SVG, saphenous vein graft.

with some debris escaping past the EPD and into the microvasculature.

Angioplasty on degenerated saphenous vein grafts (SVGs) is associated with significant embolization burden and thus served as a good clinical test setting for the hypothesis that distal embolic protection would improve clinical outcomes. The Saphenous vein graft Angioplasty Free of Emboli Randomized (SAFER) trial randomized 801 patients undergoing PCI on a SVG to the use of PercuSurge GuardWire balloon occlusion device versus standard guidewire.[99] The patients in the EPD group had a lower incidence of post-PCI myocardial infarction (8.6% versus 14.7%, $P = 0.008$) and no-reflow phenomenon (3% versus 9%, $P = 0.02$) compared with the control patients. The FilterWire EX Randomized Evaluation (FIRE) trial compared the FilterWire with the GuardWire in 651 patients undergoing SVG PCI and demonstrated a similar incidence of adverse cardiac events at 30 days.[100] These findings established the utility of distal embolic protection in vein graft angioplasty. Encouraged by the SAFER trial results, the use of EPD in angioplasty for acute myocardial infarction was evaluated in the Enhanced Myocardial Efficacy and Recovery by Aspiration of Liberated Debris (EMERALD) trial ($n = 501$).[101] Patients were randomized to GuardWire Plus balloon occlusion and aspiration system versus standard therapy, and visible debris was recovered in 73% of the interventions in the distal protection group. There were no differences, however, in microvascular function (as detected by ST-segment resolution), infarct size, or major adverse cardiac events between the two treatment groups. Given that primary PCI appears to carry a high risk of distal embolization, the EMERALD trial results suggest that embolic protection does not have the same benefits in native coronary artery PCI as those observed in vein graft angioplasty. It is possible, however, that improvements in device design might make EPD a beneficial therapy in native coronary artery angioplasty.

An alternate strategy for embolic protection is illustrated by the Proxis embolic protection system. It is the first *proximal* embolic protection system with an occlusive balloon-aspiration system placed upstream to the lesion. On balloon inflation, blood flow in the coronary artery is stopped temporarily, followed by aspiration of material that might otherwise embolize with the upcoming angioplasty.

Endovascular Radiation

Adjunctive intracoronary brachytherapy involves the placement of beta- or gamma-emitting wire ribbons next to the lesion after conventional percutaneous treatment. Following redilation of the in-stent restenosis (ISR), brachytherapy significantly reduces the risk of subsequent recurrence. In the first randomized trial of 54 patients, brachytherapy with a gamma emitter reduced the binary restenosis rate at 6 months (17% versus 54%, $P = 0.01$),[102] with the benefit sustained through 3 years[103] and 5 years, respectively.[104] Coronary brachytherapy using gamma emitter is technically demanding—requiring long dwell times—and is, therefore, rarely used. The STents And Radiation Therapy (START) trial randomized 476 patients with ISR to beta-radiation (Beta-Cath system) versus placebo and documented a reduced rate of angiographic restenosis in the irradiated segments in the treatment arm 8 months after PCI (24% versus 46%, $P < 0.001$).[105] Similar reduction was noted in the rate of target lesion revascularization (8% versus 22%, $P = 0.008$). The Intimal Hyperplasia Inhibition with Beta In-stent Trial (INHIBIT) evaluated the efficacy of the beta-emitting GALILEO system.[106] The primary endpoint of binary angiographic restenosis in the stented segment at 9 months after PCI was reduced by 67% in the treatment arm ($P = 0.0001$), and corresponding reduction was noted in the need for TLR. The anti-proliferative effect of brachytherapy is largely due to a delay in post-PCI healing. Once this effect has dissipated and healing begins (after 2 to 3 years), the process of neointimal hyperplasia may resume. The emergence of drug-eluting stents has made the use of brachytherapy quite rare. It is important to recognize, however, that vascular brachytherapy was the first effective antiproliferative treatment for in-stent restenosis.

INTRAVASCULAR IMAGING TECHNIQUES

Despite improvements in the resolution of coronary radiographic imaging, there remain inherent limitations to the use of angiography as a means of assessing coronary lesion morphology and the results of percutaneous revascularization. Coronary angiography visualizes only the opacified lumen of

the artery and is thus incapable of evaluating pathological structures within the vascular wall. Substantial atherosclerosis may develop before a reduction in luminal dimensions,[107] a process that cannot be discerned by angiographic assessment. The two-dimensional view provided by the coronary angiogram is often inadequate to appreciate the severity of eccentric or complex lesions and underestimates the degree of stenosis in the presence of diffuse coronary disease extending into adjacent "normal" segments. New modalities have thus been applied in the setting of percutaneous coronary intervention to visualize more precisely the arterial wall and the vascular lumen or to assess the functional significance of a coronary stenosis.

Intracoronary Pressure Measurement

Technical advances have led to the development of coronary guidewires with microminiaturized, solid-state pressure transducers at their tips (Radi, Uppsala, Sweden and Endosonics, Rancho Cordova, CA), allowing measurement of high-fidelity pressure gradients across a coronary lesion with the same platform used for delivery of coronary interventional devices. The pressure wire provides a physiological assessment of the functional significance of a coronary stenosis through derivation of a parameter known as fractional flow reserve (FFR). FFR is the ratio of maximal hyperemic blood flow in a stenotic artery to the maximal flow that would occur in the absence of a stenosis. This index is determined by precise measurements of pressures proximal and distal to the stenotic lesion during maximal hyperemia induced by adenosine infusion. The FFR value in normal vessels is 1.0, decreasing with increasing stenosis severity. A threshold value of 0.75 for FFR has been correlated with exercise-induced myocardial ischemia,[108] an FFR >0.94 has been associated with optimal stent deployment, and a value >0.90 with an optimal result of balloon angioplasty.

Intravascular Ultrasound

There has been rapid evolution of technology for miniaturization of high-frequency transducers to permit ultrasound imaging from within the coronary vasculature. Ultrasound energy emitted from an intraluminal probe penetrates into the vascular wall, with reflections formed at the interfaces between tissue components of different acoustic properties. Intravascular ultrasound (IVUS) thus produces high resolution cross-sectional images that not only delineate absolute luminal dimensions but also the extent and structure of the atherosclerotic plaque and the arterial wall. IVUS images have been shown to correlate well with histological findings.[109,110]

IVUS has been employed clinically to identify angiographically inapparent atherosclerotic plaque, quantify luminal dimensions, and characterize the composition of stenotic lesions (soft plaque, hard plaque, calcification, thrombus). This technique has been particularly useful in assessing the degree of luminal compromise in lesions that appear to be equivocal or indeterminate by angiography.[111,112] IVUS has contributed to our understanding of the mechanisms of balloon angioplasty[113] and new device interventions[114-116] and has been employed clinically to guide and assess the results of these techniques. Identification of certain morphologic features by ultrasound may predict the outcome of percutaneous intervention[117] and aid in the selection of the best device to obtain an optimal angiographic result.[118]

Serial IVUS examinations may also be performed during the revascularization procedure to assess interim results and guide further interventional therapy. Following percutaneous revascularization, IVUS provides a more accurate estimation of luminal dimensions than does angiography[119] and appears to be the most sensitive method for evaluating the completeness of lesion dilation, plaque removal, or stent deployment and for detecting plaque disruption or medial dissection. IVUS guidance during stent implantation is useful in optimizing postprocedural luminal area and may reduce long-term restenosis. In the CRUISE study, the cross-sectional luminal area after stenting was greater among patients whose PCI involved IVUS guidance compared with angiography guidance (mean 7.14 versus 6.25 mm^2), with a significant reduction in the late incidence of target vessel revascularization (8.5% versus 15.2%, $P < 0.05$).[120] Likewise, a meta-analysis of 9 studies and 2972 patients demonstrated that IVUS-guided PCI with stenting was associated with a lower rate of target vessel revascularization at 6 months (odds ratio 0.62, $P < 0.0001$) after the procedure compared with an angiographically guided approach.[121]

IVUS measurement of coronary artery plaque volume has been used to evaluate the efficacy of anti-atherosclerotic therapy. In the Reversal of Atherosclerosis with Aggressive Lipid Lowering (REVERSAL) trial, greater reduction in LDL-cholesterol with high-dose atorvastatin compared with pravastatin correlated with greater retardation of atherosclerosis progression as measured by IVUS.

SUMMARY

Over the last quarter of a decade, the development of new and enhanced methods of percutaneous coronary revascularization has led to considerable expansion in indications for this technique and improvements in immediate and long-term outcomes. More than 800,000 interventional procedures are performed in the United States each year, exceeding the number of bypass surgery operations. Although risk factors for acute complications and long-term restenosis certainly influence the selection of percutaneous versus surgical revascularization for individual patients, angioplasty and related device technologies can be applied when appropriate to patients in all age groups, with single-vessel or multivessel coronary artery disease, with preserved or impaired ventricular function, and with simple or complex lesion characteristics. In the hands of skilled operators and at experienced institutions, rates of procedural success should exceed 98%, and the acute complications of death, Q-wave myocardial infarction, or emergency bypass surgery should occur in less than 0.5% of patients. The majority of patients treated by percutaneous revascularization will undergo drug-eluting stent implantation, with the expectation of a 5% rate of symptomatic restenosis requiring repeat target vessel revascularization over the ensuing 9 months. Future developments in this field will be directed at more effective management of difficult coronary stenoses, such as total occlusions or degenerated saphenous vein grafts, or at modification of the adverse arterial thrombotic, proliferative, and remodeling responses that lead to long-term restenosis.

Chapter 7

Treatment with Drug-Eluting Stents

George D. Dangas

CHAPTER CONTENTS

Because symptoms from coronary stenoses are related to plaques in a coronary artery, a locally applied treatment is a reasonable therapeutic approach. Although coronary stent implantation was introduced to prevent recoil and arterial remodeling (shrinkage) after balloon angioplasty, most adjunctive medical therapy approaches remain systemic. The most successful systemic therapies involve anticoagulation and primary/secondary prevention of coronary artery disease, whereas systemic therapies aimed at restenosis have been unsuccessful. The drug-eluting stent systems have successfully realized the possibility of combining mechanical (stent) support and local drug delivery for the treatment of coronary artery disease.

DRUG-ELUTING STENT SYSTEM

The drug-eluting stent (DES) is an integrated mechanical and pharmacologic unit for local treatment of coronary artery disease. The metallic stent provides the scaffold necessary to prevent vessel recoil and unfavorable remodeling,[1] whereas the eluted drug aims to limit the neointimal proliferation, although other mechanisms may coexist (Table 7–1).

Typically, the drug is eluted from a polymer that is wrapped around a metallic surface. Although alternative types of drug-elution can also be achieved, the approved and best-studied DES systems release their bioactive agents from encapsulated, elastomeric, non-erosive, biostable polymers. The polymer limits, in some ways, the flexibility of the stent itself, thereby making delivery of a DES inside a coronary artery more technically demanding than with an identical bare-metal stent. In addition, the polymer may lead to a late local inflammatory process because it is not dissolved right after drug elution.

RESULTS OF MAIN CLINICAL TRIALS OF APPROVED DES

There are currently three DES systems that are widely used after approval for human use. Overall, the results have been remarkably consistent across DES systems and patient populations. Typically, each DES was first submitted to a small clinical trial of near-ideal isolated lesions, followed by clinical studies in patients with lesions of escalating complexity. Ultimately, unselected registry (so called "real-world") data, subset analyses, and comparative studies between DES have complemented the wealth of clinical research knowledge in the area of DES. In brief, more than 10,000 patients have been studied within this medical subject.

Sirolimus-Eluting Stent

The sirolimus-eluting stent (Cypher) was the first to be approved worldwide. The First-In-Man (FIM) investigational experience with this DES was initiated in December 1999 and a 4-year clinical and angiographic follow-up has confirmed the safety, efficacy, and durability of the clinical results (Fig. 7–1).[2] When evaluated in a multicenter setting, this DES achieved a remarkable absolute "zero" for events in the initial trial: 0 mm late loss, 0% restenosis, 0% repeat target vessel revascularization, and 0% stent thrombosis.[3,4] Such observations were quite novel for the specialty of interventional cardiology that had been accustomed for many years to negative results regarding restenosis prevention in humans with multiple agents and devices despite promising animal data and positive pilot clinical results. This inauguration of the DES "revolution" established a high level of interest on subsequent clinical results with this and other DES systems (Table 7–2).[1,5-13]

Technical Lessons from Sirolimus-Eluting Stent Studies

The pivotal multicenter randomized trial confirmed the profound suppression of neointimal proliferation (mean late lumen loss <0.1 mm, restenosis <10%) with the sirolimus DES.[5] Stent thrombosis and late aneurysm development were rare. Results were excellent within the stent area but not so remarkable in the immediate peri-stent area (i.e., when 5 mm proximal and distal to the stent edge were taken into account). The important observation was made that balloon predilation might have caused a degree of injury at arterial areas not ultimately covered with a DES. This type of "geographical miss" might indeed result in injured arterial areas that were thus prone to neointimal proliferation but did not receive

Table 7–1 Substances Tried as Anti-restenosis Agents on Drug-Eluting Stent Systems

Type of Action	Name of Active Agent
Suppression of inflammation/immune response	Sirolimus (rapamycin) Zotarolimus Everolimus Tacrolimus Other analogs Paclitaxel Taxane Dexamethasone Methylprednisolone Other glucocorticoids Interferon-γ Mycophenolic acid Cyclosporine Tranilast Probucol Biorest Leflunomide
Suppression of cell proliferation (*also including smooth muscle cell migration)	Sirolimus* and analogs (as above)* Paclitaxel and analogs (as above) Actinomycin-D Methotrexate Angiopeptin Vincristine Mitomycin C-*myc* antisense oligopeptides Ribozymes
Suppression of extracellular matrix production (or modulation of its substance)	Batimastat Probucol C-proteinase inhibitors Prolyl-hydroxylase inhibitors
Enhancement of endothelialization and vascular healing	17 β-Estradiol, other gynecological hormones Nitric oxide donors Endothelial progenitor cell chemoattractants Vascular endothelial growth factor Statins

treatment with the eluted drug. This clinical observation also confirmed the negligible drug diffusion around the DES.

As a result of this observation, a new DES-deployment protocol was developed that included special attention to cover with a DES every arterial part that was injured during balloon predilation, and also to limit balloon predilation to the shortest balloon possible, avoid slippage during inflation, and even consider direct DES implantation without predilation. Indeed, the clinical results obtained in these subsequent studies[6-8] confirmed that with adherence to the outlined implantation protocol, both the within-stent and the peri-stent arterial segment develop minimal neointimal proliferation. Further support to full-segment coverage was provided by the widely documented very minor (actually almost zero in several analyses) increase in restenosis with increased length of DES implanted. The DES deployment technique was developed after the first sirolimus-eluting studies and has been recommended since that time for all DES systems.

Paclitaxel-Polymer-Based Eluting Stent

Both the slow- and moderate-release formulations of the paclitaxel DES system entered human trials (Table 7–3),[14-19] but the development process ultimately focused on the slow-release formulation DES, which was the second DES to be approved for human use, approximately 1 year after approval of the sirolimus-eluting stent. In all clinical trials with this stent, the deployment technique mandated complete injury segment coverage, as described earlier. In many clinical trials, the TAXUS-SR stent was shown to be safe and had significantly less restenosis and repeat revascularization rates than an identical bare-metal stent. Overall, the decrease in repeat revascularization has been the most consistent finding with the TAXUS stent compared with the identical bare-metal stent in the studies performed (3% to 6% repeat revascularization procedures, 5% to 8% restenosis with DES, both down from 11% to 12% and 24% to 27% with control stents, respectively).

Circulation 2005;111:2326-29.)

DES Comparison and Clinical Implication of Late Lumen Loss

Although both of the approved DES with sirolimus and paclitaxel elution have reduced the rate of binary restenosis (defined as >50% diameter stenosis at follow-up) and frequency of repeat procedures at the treated arterial segment, the late lumen loss values after each DES differed significantly (Table 7–4).[20-26] Late lumen loss with the sirolimus-eluting stent has been 0.1 mm to 0.2 mm, although it has never approached zero with the paclitaxel-eluting stent. With the paclitaxel DES, late lumen loss ranged from 0.25 mm to 0.55 mm; this value is still significantly lower than the values of 0.8 mm to 1.0 mm typically observed after bare-metal stent implantation.

This observation has been intriguing, because a higher late lumen loss was not clearly associated with increased restenosis and clinical events,[27] thereby implying two possibilities: (1) a yet unraveled difference in restenosis and repeat revascularization that could be uncovered through dedicated clinical trials; or (2) a uniform distribution of a thin neointimal tissue layer within the paclitaxel-eluting stent that could be either progressive over time and ultimately produce late restenosis and clinical events or stagnant over time—clinically harmless and even protective from unwanted DES contact with the arterial lumen.

A series of head-to-head trials of the two stent types were conducted in an attempt to investigate the first possibility listed in the preceding paragraph.[20-26,28] All of these studies unequivocally confirmed the significantly lower late lumen loss with the sirolimus-eluting stent. Regarding binary restenosis and recurrent clinical events, the results were not so clear. Although in every trial both restenosis and clinical event rates were arithmetically lower with the sirolimus-eluting stent, not all studies produced statistically significant event reductions. The strongest results were shown in a double-

center study that included a largely unselected population (elective, stable/unstable angina and acute myocardial infarction with few lesion restrictions)[24]; whereas the less significant results occurred in a multicenter trial on less clinical acuity and lesion complexity (Marie-Claude Morice, oral presentation, ACCIS, March 6, 2005, Orlando, FL). Whether these facts truly support option 1—described earlier—remains to be verified in larger trials.

Additionally, in the absence of large studies with long-term systematic and periodic angiographic follow-ups, it is also impossible to render a definitive opinion regarding the progress of the late lumen loss disparity between the two DES types. The incidence of clinical events related to the target vessel during the long-term follow-up phase (beyond the primary endpoint assessment) of all the DES trials will be used as an important clinical surrogate when it becomes available.

Zotarolimus-Eluting Stents

The third DES approved for human use in Europe is the phosphorylcholine-encapsulated zotarolimus (also known as ABT-578)-eluting cobalt alloy stent (Endeavor Stent, Medtronic Vascular, Santa Rosa, CA).

Clinical results with the zotarolimus stent (Table 7–5)[29,30] have indicated (1) favorable safety with very low rates of stent thrombosis; (2) lower restenosis and clinically driven target lesion reintervention than an identical bare-metal stent; (3) significantly higher late lumen loss (0.5 to 0.6 mm) than the sirolimus-eluting stent; (4) similar rate of target lesion reintervention to the sirolimus-eluting stent; and (5) improved technical success (likely because of improved stent delivery) and lower periprocedural events (possibly related to technically easier procedures with a more deliverable stent, less side-branch compromise, or both). Large ongoing trials are investigating its differences to the paclitaxel-polymer-based eluting stent and its clinical results when implanted in higher-risk patients and lesion subsets.

The observations made with this DES emphasize the importance of clarifying the clinical implications of late lumen loss after DES placement.[27] The described differences between the sirolimus and the paclitaxel-approved DES systems appear to be similarly reproduced by a new DES that uses a sirolimus analog. Therefore, the profound suppression of late loss with the sirolimus-eluting stent may be particularly related to the specific compound (as opposed to its chemical class), or to a very unique and highly important combination of polymer structure and drug-delivery kinetics. It is noteworthy that a DES with late loss of 0.6 mm still produces important reductions in restenosis and recurrent events compared with a bare-metal stent with late loss of 0.5 mm to 0.6 mm at the same time that its clinical effect is not clearly inferior to another DES that has late loss of approximately 0.1 to 0.2 mm. Painstaking mathematical modeling after pooling angiographic and clinical data from all DES studies, as well as dedicated studies with periodic angiographic follow-up, may shed light on this phenomenon. Noninvasive coronary imaging with computerized tomography with enhanced in-stent imaging capability may enable the conduct of studies with serial coronary angiography and clinical follow-up blinded to the angiographic results.

Another zotarolimus-eluting stent composed of tantalum and stainless steel in a tri-layer design and encapsulated with a modified phosphorylcholine coating has been used in clinical trials—those results are pending.[1]

CLINICAL USE OF DES IN DIFFERENT PATIENT AND CLINICAL SUBSETS

DES have been mainly used in selected patient and lesion subsets before regulatory approval, which is granted for a rather narrow indication—one that does not represent more than 10% of lesions treated in contemporary interventional cardiology. Therefore, gradual accumulation of “real-world” results in unselected patient and lesion types has been historically viewed to be very important for the expansion of clinical applications of the new interventional devices. Such data have been particularly important in the DES area because of the very high expectations of interventional cardiologists from the remarkable safety and efficacy of the DES treatment shown in the preapproval trials.[1]

In general, every interventional device has somewhat less favorable results when applied in the “real-world” depending on the complexity of the device, the learning curve for its use, and the frequency of its use. DES have been used with high (and increasing) frequency and have a brief (although finite) learning curve. We have already described the quick revision of the DES implantation technique after the first large sirolimus-eluting stent multicenter trial. Had this issue not been resolved so fast, a series of prospective DES studies and many “real-world” series would have been plagued by this problem.

The performance of DES in the “real-world” has been quite satisfactory, although not as dramatically effective as in the preapproval randomized trials. A detailed analysis of DES performance within each and every patient and lesion subset is beyond the scope of this chapter, but DES patient subsets with the highest clinical importance or those that are particularly problematic compared with bare-metal stent treatment will be highlighted.

High-Risk Lesion Subsets

Lesion subsets that have been difficult to treat successfully with metal stents are long lesions,[6,31] ostial lesions,[32-34] and those in small vessels.[26,35,36] Treatment of any of these lesion types with DES has been clearly superior to bare-metal stents. In treating long lesions, the operator should provide full lesion coverage because the “restenosis penalty” is no longer proportional to stent length when a DES is used.[37-40] Particularly in vessels with a small reference lumen diameter, DES with very little late lumen loss may be more useful because late loss may correlate more tightly with binary restenosis in small vessels. Complete apposition and expansion are always important for DES implantation but are of particular importance in ostial lesions owing to the greater chance of proximal-distal vessel size disparity, eccentricity, and negative remodeling that may resist expansion.[41,42] Routine postdilation with appropriately sized noncompliant balloons is recommended in such cases.

DES implantation in diffuse disease should not be expected to yield as favorable results as in discrete lesions. Although there is not a large restenosis penalty for use of long stents, the risk of complications is high if DES is not implanted from “healthy to healthy” arterial segments. In

See Table 7–2 for acronym definitions.

diffuse disease, it may be impossible to identify the healthiest area. The occurrence of diffuse disease in small vessels typically places such patients at high risk for any revascularization procedure (DES or bypass surgery). The operator should weigh selective DES implantation at the tightest spots versus the "full-metal jacket" approach versus bypass surgery versus medical therapy in a patient with diffuse disease.[43-45]

Treatment of saphenous vein grafts has classically been a problematic area because, by definition, these patients have already failed a bypass operation and the vein grafts are particularly prone to distal embolization and other procedural complications.[46,47] Most DES are not available in sizes greater than 3.5 mm in diameter. Even with aggressive postdilation, the 3.5 mm DES cannot reliably expand more than 4.5 mm. The large size of vein grafts may not allow implantation of DES, or may lead to distal embolization during the high-pressure postdilation. Results from DES registries indicate that the clinical recurrence after DES implantation in saphenous vein grafts is markedly lower than expected with bare-metal stents; hence, DES can be used in vein grafts provided that the clinician has taken into account the technical limitations just discussed.[48-50]

Both single center registries[51-53] and a randomized study (Maarten J. Suttorp, oral presentation of PRISON-II study at TCT, October 17-21, 2005; Washington, DC) have indicated marked restenosis reduction with DES compared with bare-metal stents in chronic total occlusions. Again, this lesion subtype had been related to increased restenosis and reocclusion after angioplasty, with modest improvement with bare-metal stents. Advances in wire technique and technology that enable greater success in crossing the occlusion have energized the attention to this lesion type.[54,55]

Bifurcation and Left Main Coronary Artery Lesions

A frontier not explored extensively with bare-metal stents owing to high restenosis and recurrent clinical events includes bifurcation and left main coronary artery lesions. The initial enthusiasm with DES in bifurcation lesions was concurrent with the development of the "crush" technique for deployment of DES in both the parent and the daughter vessels.[56,57] Despite encouraging early results, routine deployment of two DES in bifurcations is currently not recommended, because the restenosis in the daughter vessel has been as high as 20%, along with a very low restenosis in the main vessel (Fig. 7–2).[58] A provisional stent approach should be used, with the decision to deploy a DES also in the daughter vessel in case of a persistent high-grade stenosis dissection or a moderate stenosis in the presence of an unfavorable take-off angle after balloon predilation.[56]

A relation between bare-metal stent restenosis and sudden cardiac death had been raised in certain left main series and never definitively proved or negated.[1] Therefore, the emergence of a very low restenosis rate with DES reintroduced the concept of left main stenting, especially because its large vessel size would place the left main coronary artery in the most favorable lesion subset. Indeed, initially encouraging results have been obtained with restenosis <10%.[59] The outcome is dependent on the lesion location: an ostial or main body lesion that can be covered by a DES without any involvement of the left main bifurcation is considered the most favorable lesion type. Involvement of the bifurcation introduces several technical issues depending on the exact regional anatomy.[60-62] In such cases, the techniques vary significantly worldwide: single DES into the proximal left anterior descending artery with "jailing" of the circumflex artery is mostly followed in Asia, the T-stent or simultaneous "kissing" stent deployment has been considered in Europe and the United States according to treatment of other lesions within the left anterior descending and circumflex arteries. A dedicated international left main DES (with the sirolimus-eluting stent) versus bypass surgery trial is underway. At this point, routine angiographic follow-up should be recommended at 4 to 6 months and 12 to 14 months postprocedure for every patient who receives a left main DES. In this patient subset, preoperative clearance for high-risk noncardiac surgery at any later time should reasonably include repeat coronary angiography.

Multivessel Disease and Diabetes

The most interesting and controversial patient and lesion subtypes include the use of DES for diabetic patients and multivessel coronary artery disease. The initial multicenter results of DES use in diabetic patients (under 25% of any trial had diabetes) were controversial,[5,6,18] but subsequent randomized trials have actually shown lower restenosis and clinical events with the sirolimus-eluting stent compared with bare-metal[63] and paclitaxel-eluting stents.[23] The comparative DES study results should be considered preliminary, and verification in another study should be sought; registry data are also generated.

The use of DES in multivessel disease (25% diabetics were included in the cohort) was studied in the Arterial Revascularization Trial Study part II (Fig. 7–3).[64] In this study, identical inclusion and exclusion criteria to the ARTS-I trial[65] were used to develop a study group treated with multiple sirolimus-eluting stents. This DES cohort included more diabetics (25%), longer lesions and stents, and more lesions and stents per patient compared with the ARTS-I trial. Compared with the ARTS-I bare-metal stent group, lower stent thrombosis and periprocedural events were documented (the use of glycoprotein IIb/IIIa inhibitors was also significantly higher in the DES group) and superior long-term major adverse cardiovascular event rate was observed. The long-term results available thus far were superior even to those documented in the bypass surgery group of the ARTS-I trial according to Bayesian analysis.[64] A 3- to 5-year follow-up is expected.

These results have provided the rationale for two ongoing prospective trials. One study [SYNergy between Percutaneous Coronary Intervention with TAXus and Cardiac Surgery (SYNTAX)] compares the implantation of TAXUS-SR with bypass surgery in patients with multivessel disease (also allowing inclusion of patients with stenotic left main lesions) with a 1-year cardiovascular event rate primary endpoint and 5-year subsequent follow-up. The other study (Future REvascularization Evaluation in patients with Diabetes mellitus: Optimal Management of multivessel disease [FREEDOM]) compares the implantation of any approved DES (either sirolimus-eluting or paclitaxel-polymer-based-eluting stent up to now) with bypass surgery in patients with diabetes mellitus and multivessel coronary artery disease (excluding left main); there is a 3-year primary endpoint of death, nonfatal myocardial infarction, or stroke.

Acute Coronary Syndromes

Owing to initial prothrombotic concerns with use of DES, clinical results of DES in patients with an acute coronary syndrome (ACS) became critically important. Several results to date have indicated that DES implantation in ACS patients is safe and effective.[12,66,67] Particularly for unstable angina, there is no controversy and the use of DES is well accepted. Some controversy still exists regarding DES use in the acute phase of ST-segment elevation myocardial infarction; this has been sparked mostly by sporadic, single-center experiences rather than by clinical study results.[68,69] Given that many factors can potentially affect the occurrence of stent thrombosis[70] in primary or rescue angioplasty, and given that there are fewer patients with myocardial infarction than with unstable angina, this controversy is to a certain extent expected because of the event rate variability from center to center. In several "real-world" registries, and in a large, double-center European study comparing two DES types in unselected patients including ACS, no adverse events were noted in the myocardial infarction subset.[24,69,71-73] A large, ongoing multicenter trial of primary angioplasty in acute myocardial infarction randomizes the paclitaxel-polymer-based-eluting stent to identical bare-metal stent and will provide invaluable clinical insights.

IN-STENT RESTENOSIS

Vascular Brachytherapy

The only device formally approved for treatment of bare-metal in-stent restenosis is vascular brachytherapy. However, its complex multidisciplinary set-up and the disappointing late recurrence rates[74] in comparison with the ease of use and favorable results of DES have contributed to the world-wide abandonment of brachytherapy. Furthermore, randomized trial results have shown superior results with DES than with brachytherapy for bare-metal stent restenosis (see Table 7–2).[75]

A compassionate use registry of sirolimus-eluting stent included only "no-option" patients.[76-78] The subset of patients who had failed brachytherapy (administered for prior bare-metal stent restenosis) and were subsequently treated with DES had significantly worse outcomes (>25% major adverse event rate) than the remaining high-risk patients. Based on these results, treatment with DES after brachytherapy is generally discouraged; it could be considered only for focal recurrence or if the possibility of bypass surgery does not exist and periodic angiographic follow-up should be recommended. Because vascular brachytherapy is no longer used, this problem will be seen progressively less frequently.[79]

DES for Bare-metal Stent Restenosis

Use of DES for in-stent restenosis as first-line therapy (i.e., without prior brachytherapy) has been studied in registries, subgroups of major trials, and dedicated randomized studies.[16,22,80-82] The results indicated a favorable efficacy and safety; however, there are some caveats that should be highlighted.

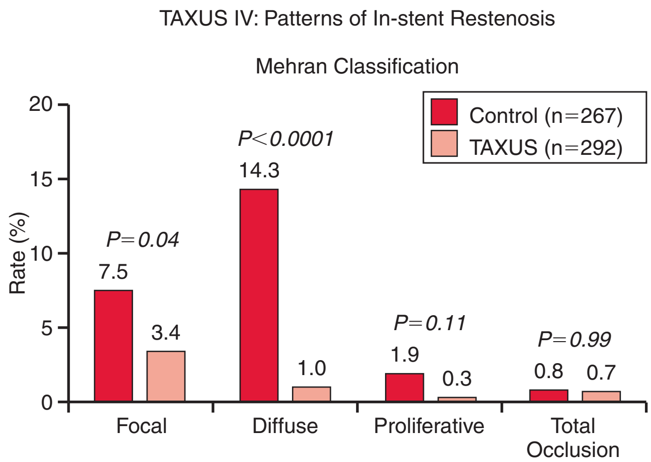

Figure 7–4 Not only do DES reduce restenosis, but they also shift the distribution of recurrent in-stent restenosis pattern to predominantly focal presentation. (Redrawn from Iakovou I, Schmidt T, Ge L, et al: Angiographic patterns of restenosis after paclitaxel-eluting stent implantation. J Am Coll Cardiol 2005;45[5]:805-6.)

In treating in-stent restenosis, it is important to understand its mechanism,[83] stent under-expansion, and other local mechanical complications. Edge restenosis versus excessive neointimal proliferation within a well-expanded stent can be differentiated with intravascular ultrasound imaging. Patterns of in-stent restenosis are shown in Figure 7–4.

When necessary, optimization of stent expansion with high-pressure balloon inflation should be undertaken first. If stent expansion does not improve, further treatment with DES or bare-metal stent is not indicated and could be harmful owing to the possibility of thrombosis at the site of spot of stent underexpansion. In such unusual, high-risk cases the operator should evaluate (depending on lesion location, vessel size, and overall patient condition) the options of balloon angioplasty alone, bypass surgery, or advanced interventional techniques with rotational ablation of the old stent struts and the rigid-calcified plaque behind them to allow appropriate expansion of the new stent.

If restenosis occurs at a stent edge or when the original stent is well expanded (or after its expansion is successfully improved with high-pressure balloon dilation), treatment with DES is currently considered the treatment of choice with complete lesion segment coverage. Lesion subsets that are specifically problematic when restenosed are the bifurcation lesions originally treated with two stents. In such cases, the metallic configuration at the bifurcation may be precluding any stent advancement into the side branch and the treatment with DES may not be as helpful owing to potential local underexpansion due to the amount and configuration of "old" metallic stents.

DES Restenosis

Although rare, restenosis still occurs after DES implantation and warrants specific management plans. An important observation from randomized DES trials is that in the restenosed lesions, the lesion length is significantly shorter after DES than after bare-metal stent implantation.[84-86]

Accordingly, DES restenosis is mostly focal (>85% of cases), whereas bare-metal restenosis is mostly diffuse (>65% of cases). Because focal in-stent restenosis has a far better response to subsequent treatment and prognosis than do diffuse, proliferative and occlusive patterns, DES restenosis appears more favorable than bare-metal stent restenosis.[69]

Intravascular ultrasound imaging can help identify reasons for DES restenosis. Attention should be paid to the same issues as just described regarding original stent underexpansion.[87] Other morphological issues that may be revealed with such imaging are (1) stent malapposition,[88] which should be corrected when associated with restenosis; (2) stent fracture, which may occur infrequently at bend points or at stent overlap that may require additional DES implantation[89]; (3) incomplete lesion coverage that manifests as edge restenosis[90] while the entire original stent is actually free of intimal hyperplasia; and (4) a gap between two DES that requires coverage.

Treatment of DES restenosis should be guided by an understanding of the local morphology as outlined, and in general includes implantation of new DES of the same type in cases of focal restenosis, edge restenosis (with previously incomplete lesion coverage), stent gap, or fracture. Typically, the new DES should be as short as possible but still respect the rule of complete segment coverage. In restenotic cases within the main stent body due to focal underexpansion or intimal hyperplasia, local treatment with a noncompliant (high-pressure) balloon, or preferably with a cutting balloon, could be attempted and implantation of a new DES could be reserved for failures of this approach.[91]

In cases of diffuse in-stent restenosis lesions that can be clearly covered by additional DES (i.e., obvious proximal and distal "healthy" landing zone), use of an alternative DES type can be considered[92] if intimal hyperplasia is the dominant mechanism. This may be helpful because a different antiproliferative drug would be eluted locally (at a site that demonstrated "resistance" to the originally eluted drug), but the lack of well-documented benefits and risks of this approach need to be clearly understood. In our practice, we have not noticed obvious early or late adverse events.

Intravascular ultrasound imaging has indicated that there is an adverse interaction between small final stent cross-sectional area at the time of original DES implantation and stent length, with the highest restenosis chance when the area is under 5.5 cm^2 and the length longer than 40 mm (17% with both factors present versus 0.4% with both factors absent).[93] Therefore, clinicians should pay detailed attention to DES expansion when restenosis occurs in long DES.

High-risk DES restenosis cases necessitating the consideration of bypass surgery include complex configuration of multiple restenosed DES (especially in bifurcations), many DES layers due to repeat restenosis, or any involvement of the left main bifurcation.

DES THROMBOSIS

DES thrombosis has been highlighted in various forms since the introduction of DES because of its severity and despite its rarity.[93-98] Local thrombogenicity may arise from several factors including metallic stent type configuration (wall coverage, tissue prolapse , side-branch compromise), polymer, type of eluted agent and local dosage, antithrombotic therapy, and patient-lesion characteristics. A specific underlying mechanism pertinent for DES is the time to achievement of complete endothelialization, which is extremely difficult to assess in vivo.[99] To account for this factor, DES implantation is performed with the recommendation to follow an extended period of dual antiplatelet therapy.

Initial clusters of subacute thrombosis were documented sporadically shortly after introduction of DES in clinical practice but this problem reduced in frequency with additional experience and adoption of complete disease segment coverage with the DES, and detailed attention to apposition, expansion, and overlap zones. No DES randomized trial documented excess stent thrombosis compared with control bare-metal stent.

Interestingly, certain studies found an excess (with weak statistical significance) of thrombosis with the paclitaxel polymer-based DES compared with the sirolimus-eluting DES.[28,100] Clearly, the very low frequency of thrombotic events has made firm conclusions very difficult to achieve, and the design of a definitive trial would require an extremely large number of patients. Similarly, an initial report of acute intraprocedure thrombosis during DES implantation[101] has not been corroborated by other reports, and this problem is no longer considered a significant issue.

A large "real-world" registry focused on patient and lesion characteristics that may predispose to DES thrombosis, with premature interruption of dual antiplatelet therapy being by far the leading such factor (29%); other important factors include previous brachytherapy (see earlier), chronic renal failure, bifurcations, unprotected left main coronary artery, diabetes, and acute coronary syndrome (with descending rates of 8.7% to 1.3%).[100]

At the i2/ACC-2006 conference (March 7-11, 2006, Atlanta, GA), two randomized studies from Europe addressed the issue of DES versus bare metal stenting in acute myocardial infarction (Christian Spaulding and Marits Dirksen presenters). The stent thrombosis rates were similar between DES and control, but one of the studies reported those rates to be 3% to 4%, which is higher than expected. This raises again the possibility of an underestimation of thrombosis rates after bare metal stenting because of the familiarity with these devices and the rarity of the events. Nonetheless, this underlies the significance of adjunctive pharmacologic therapy for high-risk stent procedures.

The time course of stent thrombosis after DES appears to be more extended than after bare-metal stenting. Following bare-metal stenting, a steep decrease was noted after 2 weeks and a near-elimination after 1 month, although sporadic cases long after implantation still existed.[1] Following DES, the first month is still an important time point, with a decreased incidence between 1 and 3 months, a finite incidence between 3 and 6 months (<1% over 3 months), and sporadic cases thereafter (<1%). Because the incidence of DES thrombosis is similar overall to or just marginally higher than that seen with bare-metal stent (by 0.5%), these time-related fluctuations are quite difficult to establish definitively as unequivocal facts. It is difficult to meaningfully analyze the precise causes and risk factors of each individual case. In most instances, multiple factors contribute including influences from the DES device, patient, lesion, and pharmacologic therapy.[1,100]

With more time elapsed since DES approval, there is extended long-term follow-up available that has led to the

observation of occasional, unusual occurrence of late (>1 year after implantation) DES thrombosis, in association with the absence of dual antiplatelet therapy or a noncardiac thrombogenic stimulus.[100,102,103] Again, the rarity of such events and the absence of adequate control groups provide unsurpassable methodological limitations that preclude a definitive ruling. However, the intrinsic theoretical DES thrombogenicity and delayed endothelialization, both of which may have varying clinical significance in different patients, lesions, and clinical situations, necessitate the formulation of certain "expert" recommendations that will be discussed later in the adjunctive pharmacology section.

Treatment of DES thrombosis is based on previous knowledge from bare-metal stent thrombosis. Immediate fibrinolytic therapy (if an acute ST-elevation myocardial infarction occurs at a hospital without interventional cardiology services or the ability to transfer promptly), or therapy with heparin and glycoprotein IIb/IIIa inhibitor followed by immediate angioplasty are generally indicated depending on the location of the original stent and other patient-lesion characteristics. Intravascular ultrasound imaging can offer valuable information regarding stent malapposition, underexpansion, dissection, or incomplete lesion coverage with plaque rupture at an adjacent nonstented spot. Any of these situations warrants specific interventional approaches, and if they are not addressed properly, they will lead to further thrombotic complications. Overall thrombus load may selectively necessitate the use of thrombectomy devices. These devices should not be used routinely and without angiographic thrombus. Aortocoronary bypass surgery should be an option after the acute myocardial infarction phase in cases with suboptimal interventional results at the thrombosed segment in the presence of viable myocardium and in cases with several other unrevascularized territories.

ADJUNCTIVE PHARMACOLOGIC THERAPY

This section will address the pharmacologic therapy issues during DES implantation in various clinical and anatomic scenarios. The selection of the type of stent for any of these situations is beyond the scope of this chapter. This should not be interpreted as if DES were routinely indicated in all patients who belong in the clinical situations discussed hereafter.

Preprocedure and intraprocedural pharmacologic therapy during DES implantation should follow the recommendations for bare-metal stent implantation.[104] Early preprocedure establishment of aspirin and clopidogrel therapy is critical (at least 3 days in advance whenever possible), and a loading dose of clopidogrel (600 mg on the day of the procedure or 300 mg on the day before) should be given (Figs. 7–5 through 7–7). Heparin, bivalirudin, and glycoprotein IIb/IIIa inhibitors should be used intraprocedurally,[104] with the understanding that limited data exist on the use of these agents with DES. In a largely unselected prospective DES registry with 1-month follow-up, bivalirudin showed a favorable safety profile[105]; use of this agent should be

specifically considered in patient subsets at high risk for bleeding complications.[106]

The indication for use of bivalirudin without a glycoprotein IIb/IIIa inhibitor for treatment of acute coronary syndromes stems from the ACUITY trial (Gregg W. Stone, MD, oral presentation at i2/ACC-2006 conference, March 7-11, 2006, Atlanta, GA). Use of this agent upon admission or transfer was associated with significantly less bleeding and similar ischemic protection compared with heparin plus a glycoprotein IIb/IIIa inhibitor. Of note, this is the first large acute coronary syndrome study wherein the PCI treatment included DES in a large proportion (>50%) of patients.

ACS patients treated with early glycoprotein IIb/IIIa inhibitor therapy should be maintained on these agents throughout the DES implantation procedure (see Figs. 7–6 and 7–7). Amendments of general guidelines regarding combination anticoagulation strategies are drawn from clinical trials that do not specifically demand DES use, but glycoprotein IIb/IIIa inhibitors should be specifically considered in all DES case subsets at high risk for stent thombosis (see earlier). Although no specific data have shown reduction of DES thrombosis with these agents, abciximab has decreased thrombosis after non-DES intervention in the highly thrombogenic state of acute myocardial infarction; interestingly, in this setting, bifurcation lesions were also found to predict early (within 1 month) thrombosis.[70] After completion of the DES implantation procedure, continuation of heparin, enoxaparin, or bivalirudin is no longer necessary and glycoprotein IIb/IIIa inhibitor infusion (when such agents have been used) should be continued for 12 to 18 hours.

A clinical trial reported specifically on the benefit of abciximab in patients with troponin (+) acute coronary syndrome who have been managed with aspirin, 600 mg of clopidogrel, and heparin until arrival at the catheterization laboratory.[107] The abciximab arm had 25% less adverse cardiac events. In such patients, abciximab has a more robust body of data than other glycoprotein IIb/IIIa inhibitors. DES were used in approximately one half of the enrolled population. No significant benefit of abciximab was documented in troponin (–) patients; hence, the use of glycoprotein IIb/IIIa inhibitors in such patients may not be necessary unless other high-risk features are present.

A recommendation for oral antibiotic prophylaxis before minor surgical procedures during the first 3 months after stent implantation has been customarily included in our practice. This is based on the low treatment risk and the potentially grave outcome of endovascular stent infection despite the absence of specific data that substantiate the necessity of such recommendation. It should be noted, however, that cardiac stent infection has not been noted even in the presence of sepsis.

Long-Term Antiplatelet Therapy

Because the time course of DES thrombosis can be more extended after implantation, although its incidence is similar or only marginally higher than after bare-metal stent, long-term oral antithrombotic therapy is particularly critical. Almost concurrently with the clinical approval of DES, data emerged favoring the prolonged duration of dual antiplatelet therapy (with aspirin plus clopidogrel) after bare-metal stent implantation either electively[108] or in the context of an ACS.[109] Given the initial thrombosis concerns with DES, these findings were quickly adopted in DES treatment recommendations that were included in essentially all DES clinical trials. Accordingly, the ACC/AHA PCI guidelines recommend treatment with aspirin 325 mg and clopidogrel 75 mg for 3 months for the sirolimus stent and 6 months for the paclitaxel stent.[104]

In clinical practice, our recommendation includes a reduction of the aspirin dose from 325 mg to 81 mg after the first month (in an attempt to limit minor bleeding) and extension of clopidogrel therapy for at least 1 year (and potentially even longer if no specific adverse reactions arise). The ACC/AHA PCI guidelines advise a 3- to 6-month course of 325 mg of aspirin in addition to clopidogrel; this recommendation stems from the original DES pivotal studies[5,17] and is not based on any evidence of superiority over the 81 mg dose of aspirin and has not altered our clinical practice as stated.

Long-term compliance should be highlighted to the patient, especially because stent thrombosis (despite its rarity) can be a truly major cardiac event. It is not unreasonable to state that if patient noncompliance has been a clearly documented issue in the medical history, DES therapy may need to be withheld. Bare-metal stent restenosis is a far less morbid condition than the rarer DES thrombosis; all health care providers should be engaged in this type of risk-benefit discussion on an individualized patient basis.

A specific case that warrants clarification is the treatment after DES placement in patients who are on long-term anticoagulation with warfarin. After bare-metal stent placement, lifelong aspirin dose of 81mg, plus warfarin with unmodified target international normalized ratio plus 1 month treatment with clopidogrel has been generally recommended to provide adequate anticoagulation for both conditions, with the understanding that the higher bleeding risk would be limited only to the first month. This risk can be considerably high if the triple therapy is to be prolonged to 6 to 12 months after a DES. For this reason, patients who require a very high international normalized ratio for unusual conditions or multiple valve replacement may not be the best candidates for treatment with multiple DES. Lower risk patients with atrial fibrillation may be treated with triple therapy, but tight control of the international normalized ratio 2.0 to 2.5 is recommended.

Medication Allergy

Specific issues can arise in cases of antiplatelet medication allergy (Fig. 7–8). Desensitization should be performed for elective cases.[104] For patients with an absolute aspirin contraindication, cilostazol 100 mg twice daily may be used in combination with clopidogrel. Ticlopidine 250 mg orally twice daily can be used for patients with an absolute clopidogrel contraindication, with the understanding of the need for periodic complete blood count checks and of the possible development of ticlopidine allergy.[110,111] In case of a contraindication to both ticlopidine and clopidogrel, then cilostazol may be used in combination with aspirin and with the understanding that the antiplatelet coverage may be suboptimal long term. If such a situation is known, preprocedure use of glycoprotein IIb/IIIa inhibitor and avoidance of DES should be considered, especially if complex patient, lesion, or clinical situations coexist. If medication allergy is suspected early post-DES implantation, the first actions should be (1) establishment of diphenydramine regimen; (2) steroid therapy; and (3) exclusion for other allergy causes (other new medication

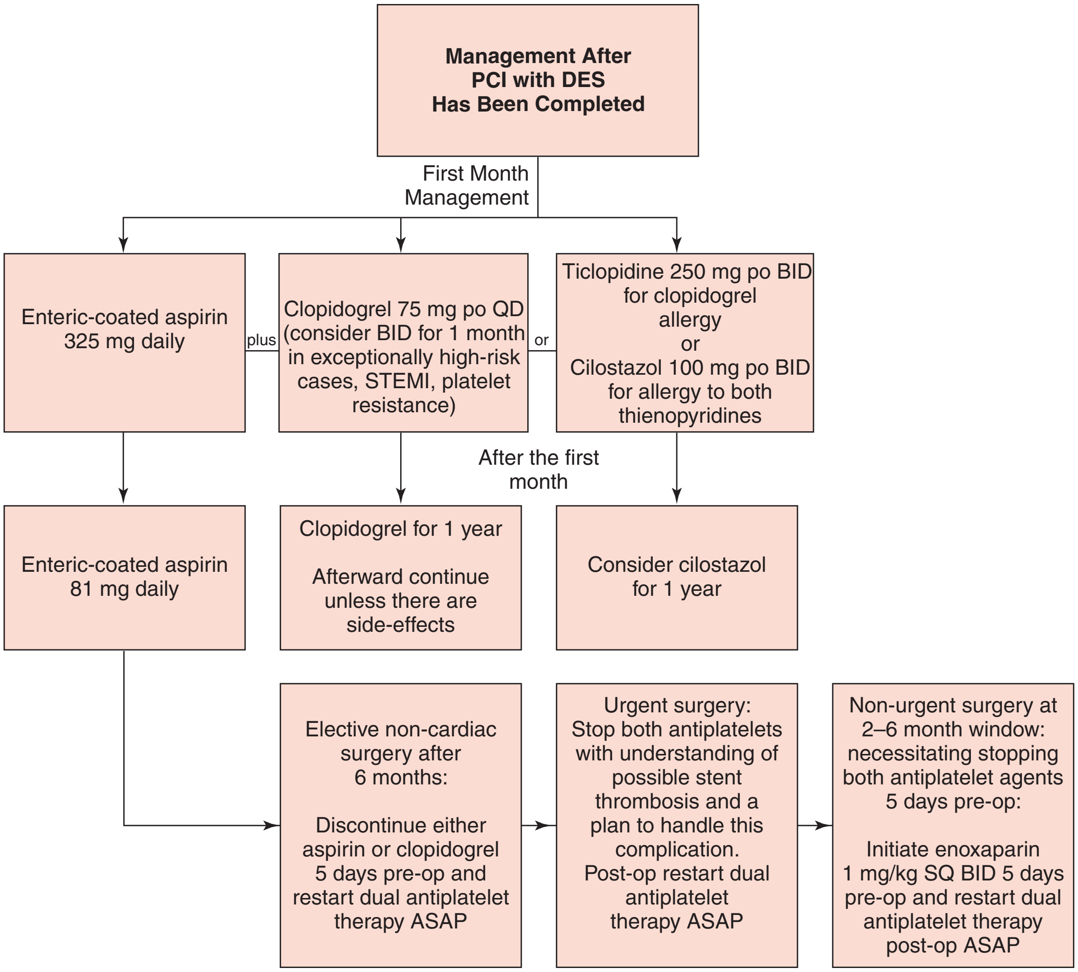

Figure 7–8 Algorithm for medical management of a patient who has been treated with a percutaneous coronary intervention (PCI) and received a drug-eluting stent (DES). ASAP, as soon as possible; BID, two times daily; SQ, subcutaneously.

or delayed contrast media reactions) rather than simple discontinuation of aspirin or clopidogrel. Clinicians should be extremely reluctant to change antiplatelet therapy within the first month after a DES and this reluctance should extend to 1 to 3 months if at all possible. Patients with an absolute need for changes in antiplatelet therapy in these time frames should be under frequent cardiologic follow-up. Finally, data on triple antiplatelet regimen are emerging.[112]

Antiplatelet Therapy Interruption

After DES implantation, the patient and family should be clearly informed that discontinuation of either antiplatelet drug should be undertaken *only* after a clear discussion of the matter with the interventional cardiologist who performed the DES procedure. This may occasionally be necessary owing to bleeding complications or surgery. The approach to each one of these situations should be individualized.

Severe (life-threatening) bleeding complications necessitate prompt interruption of all antithrombotic medications. Patients who have received DES are of particular concern because of the risk of stent thrombosis, especially if the antiplatelet agents are discontinued close to the time of DES implantation. The cause of bleeding should be evaluated and rectified as soon as possible (e.g., ulcer cauterization, packing of the nose for epistaxis) and antiplatelet therapy resumed as quickly as possible. Regular cardiology follow-up is necessary during the entire work-up of the bleeding complication. Because of the complicated nature of antiplatelet therapy interruption, preventive use of proton-pump inhibitors should be considered in patients at risk for gastrointestinal complications.

Performance of cardiac surgery under dual antiplatelet therapy is thought to have high bleeding complications. Although this has not been unequivocally documented, it is a matter of controversy in cardiothoracic surgical programs, and many surgeons recommend aspirin monotherapy for 3 to 5 days preoperatively with concomitant use of anticoagulation with heparin until the day of operation. Once a bypass procedure is performed, the issue of DES thrombosis may no longer be clinically relevant and postoperative antiplatelet therapy can be modified more liberally on an individualized patient basis. The status of antiplatelet therapy must be ascertained before patient discharge after careful review of the angiogram, DES implantation locations, and bypassed vessels.

Performance of non-cardiac surgery is much more complicated (see Fig. 7–8), because there is additional postoperative prothrombotic risk. In addition, the operative bleeding risk may vary significantly between procedures. Requests for complete interruption of all antiplatelet therapy 7 to 10 days

preoperatively should be routinely rejected in patients with DES, especially if complex patient, lesion, or clinical situations coexisted at the time of implantation. Direct communication between the surgeon and the cardiologist should explore possibilities to perform the surgical procedure (biopsy or operation) while antiplatelet monotherapy is continued, skipping one dose on the day of the procedure. The second antiplatelet drug could be interrupted 3 to 5 days preoperatively and resumed just after the operation. Procedures that would pose extended restrictions to oral intake postoperatively pose particularly high risk for DES thrombosis. The time of operation in relation to DES implantation is also very important. All elective surgery should be postponed for 6 months after DES placement. A relatively urgent operation with very limited need for pre- and postoperative antiplatelet therapy interruptions could be performed 2 to 3 months after DES placement in low-risk patient and lesion subsets. Emergency operations should be performed under close cardiology consultation. The remaining variety of intermediate urgency and risk cases should be performed with individualized arrangements agreed on by the surgeon and the cardiologist after taking into account the aforementioned recommendations.

FUTURE DIRECTIONS

Development of new DES systems is a topic of intense preclinical and clinical research. The limitations of the current DES systems frame the direction for future research. Improved efficacy in the high-risk patient, lesion, and clinical syndrome subsets is needed. The perception of marginally higher tendency for thrombosis with DES requires strict long-term compliance and poses questions regarding the adjunct pharmacotherapy as well as serial practical issues during subsequent treatment options—even for noncardiac diseases.

New DES research is investigating ways to make these devices even better through (1) improvements of the stent platform to facilitate the technical aspects of the procedure; (2) modifications of the polymer system to decrease potential adverse long-term local effects and improve controlled drug-delivery; and (3) experiments with newer generations of active substances or combinations with a second antithrombotic or vasculoprotective compound.

Regulatory approval of any modified device is not, however, as simple as previously granted approvals for advanced bare metal stent generations. A new DES system should be proved clinically to be non-inferior to an existing approved DES, and it should at the same time address at least one of the limitations of the current DES to have a meaningful role (see Chapter 4). The continuously elevated requirements for approval and clinical use undoubtedly pose hurdles to fast approval of new DES, but at the same time contribute to enhanced device safety and efficacy and have the potential to benefit increasingly more patient subsets and clinical conditions.

Revascularization Options for Ischemic Heart Disease: Coronary Artery Bypass Grafting and Percutaneous Coronary Intervention

Oon C. Ooi, Charles J. Mullany, and Charanjit S. Rihal

CHAPTER CONTENTS

Coronary artery bypass grafting (CABG) and percutaneous coronary intervention (PCI) are the most commonly performed major procedures in the world today. It is estimated that approximately 550,000 CABG and 1,000,000 PCI procedures are now performed each year in the United States, and that these interventions account for a significant proportion of health care expenditures. Estimated health care costs associated with treatment of coronary artery disease (CAD) and revascularization range from \$12 to \$20 billion each year.[1] As a consequence, CABG and PCI have undergone intense scrutiny by the public, medical profession, governmental organizations, and third-party payers. Large national databases have been gathered to monitor outcomes of individual physicians, hospitals, and regions and to ensure quality improvements where necessary. In 1989, the Society of Thoracic Surgeons (STS) established a national database for cardiac surgery.[2] This database now contains information regarding cardiac surgical procedures in more than 2.2 million patients who had surgery during a 10-year period (1995 to 2004), and of these, 73% underwent isolated CABG. Similar databases also exist for PCI. These include the American College of Cardiology National Cardiovascular Data Registry (ACC-NCDR) with 6-year data on 800,000 patients, and the New York State Coronary Angioplasty Reporting System database.[3,4] Numerous publications and initiatives have been based on these surgical and angioplasty databases.

There are three broad indications for myocardial revascularization: to improve prognosis (probability of survival); to improve symptoms; and to prevent nonfatal events such as myocardial infarction (MI), arrhythmias, or heart failure. Indications for revascularization and comparisons of modes of revascularization have been well studied in large national databases and prospective randomized clinical trials and, for many patients, selection of treatment is often clear cut and well established. However, as pharmaceutical and interventional therapy evolves, the best form of revascularization continues to be debated for a significant number of patients.

EFFECTIVENESS OF REVASCULARIZATION: CABG

The early randomized trials of the 1970s first established CABG as an effective treatment for angina pectoris. These trials included the European Coronary Artery Surgery Study (ECSS),[5] the Veterans' Administration Cooperative Study (VA),[6] and the Coronary Artery Surgery Study (CASS).[7] The outcomes of these studies indicated that CABG was more effective than medical therapy in relieving angina pectoris and that bypass surgery improved the likelihood of long-term survival in patients with >50% left main stenosis and triple-vessel disease, particularly with decreased left ventricular function (ejection fraction [EF] <50%), and in patients with two-vessel disease and a left anterior descending (LAD) artery stenosis >50%. However, these early trials tended to include low-risk patients, and only 20% of these patients had an EF <50%. Almost all patients were males between 40 and 60 years of age, and medical therapy was limited to nitrates and β-blockers. At that time, aspirin and lipid-lowering agents were not in general use for patients with coronary artery disease.

The mean age of patients undergoing CABG is now 68 years,[2] and these patients are more likely to have diabetes mellitus, renal impairment, hypertension, cerebrovascular disease, chronic lung disease, impaired left ventricular function, extensive triple-vessel disease, and to have undergone an earlier procedure—usually percutaneous revascularization with or without stent deployment. Since these early trials, there have been significant advances in the medical, percutaneous, and surgical management of CAD. β-Blocker use is now more widespread, and the introduction of newer antiplatelet agents, HMG-CoA reductase inhibitors, and ACE inhibitors has revolutionized the medical management of these patients. Percutaneous revascularization techniques are now common and continue to evolve with advanced technology, improved operator skills, uncoated and coated stents, adjuvant therapy, and bradytherapy. The operative and perioperative management of patients who undergo bypass

surgery has also improved, with greater use of arterial grafting, less invasive procedures, and better attention to secondary prevention. Whereas at the time of the CASS study only 14% of patients received an internal mammary artery (IMA) graft,[7] almost all patients now undergoing CABG receive at least one arterial graft, usually the left IMA.

EFFECTIVENESS OF REVASCULARIZATION: PCI

PCI versus Medical Therapy

A meta-analysis of six prospective randomized clinical trials (RCTs) (see Chapter 1), compared balloon angioplasty and medical therapy and involved 1904 patients with nonacute coronary artery disease.[8,9] Among low-risk patients with symptomatic coronary artery disease (CCS class II or greater angina and average mortality <1% per year), balloon angioplasty clearly provided superior control of angina pectoris but was associated with a greater need for subsequent CABG. There was no significant impact on subsequent death, MI, or subsequent balloon angioplasty. These data suggested that balloon angioplasty was indicated if the desired level of anginal relief and physical activity could not be achieved with medical therapy alone and that prophylactic balloon angioplasty could not be recommended for the treatment of coronary artery disease in the absence of angina or ischemia.[9] However, most of these studies were undertaken before 1997 and reflected practice patterns that were prevalent at that time. Initial experience with balloon angioplasty was plagued by restenosis, with a need for repeat procedures of up to 34% of patients at 1 year.[10]

Bare-Metal Stents

The high incidence of restenosis after balloon angioplasty was initially addressed with the introduction of bare-metal stents (BMS). Initially introduced for the treatment of coronary dissections after balloon angioplasty, BMS were rapidly adopted by clinicians for routine use during balloon angioplasty, thus leading to immediate improvements in procedural safety and success. In particular, the rate of emergency CABG fell from about 5% to <1% and angiographic success became routine and independent of lesion morphology. The short-term therapeutic effects of these stents have been evaluated in several trials[11-13] and, although restenosis was significantly reduced, it continued to be a significant clinical problem following angioplasty (Fig. 8–1).[11] A meta-analysis of 25 randomized clinical trials involving BMS versus balloon angioplasty, by the National Institute of Clinical Excellence for the National Health Service of the United Kingdom, found that there were no significant differences in the overall mortality rates or the incidence of MI at 4 to 11 months of follow-up. More importantly, however, stent deployment lowered the probability of repeat revascularization procedures by nearly 50% (12.4% versus 20.6%).[13]

Drug-Eluting Stents

Despite the introduction of BMS, restenosis continued to be the chief limiting factor of percutaneous revascularization. Consequently, numerous agents have been used as stent

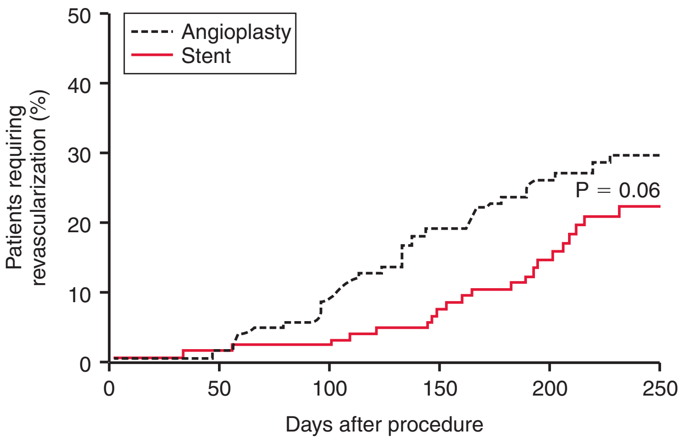

Figure 8–1 Kaplan-Meier curves for revascularization of the target lesion. Fewer patients in the stent group than in the angioplasty group required revascularization of the target lesion because of ischemia. (Adapted from Fischman DL, Leon MB, Baim DS, et al: A randomized comparison of coronary-stent placement and balloon angioplasty in the treatment of coronary artery disease. N Engl J Med 1994;331:496-501, with permission.)

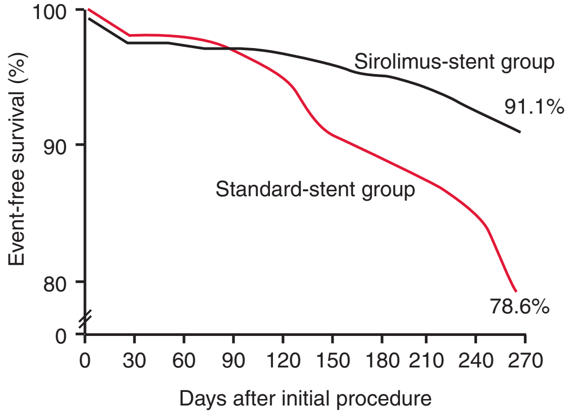
coatings in the hope of preventing thrombosis, neointimal proliferation, and subsequent restenosis. These included antithrombotic (heparin), antiproliferative (paclitaxel, actinomycin-D), immunosuppressive (sirolimus) and anti-inflammatory (dexamethasone) agents. Nondrug polymers (e.g., phosphorylcholine, which inhibits platelet aggregation) have also been used. Two agents, sirolimus and paclitaxel, are now approved as antiproliferative drugs for drug-eluting stents (DES).[14] The polymer used to bind the drug in the DES controls the rate of release of the drug into the arterial wall. All currently approved DES are a device-polymer-drug combination.

Midterm results from several randomized clinical trials and a meta-analysis of DES versus BMS suggest that, compared with BMS, DES substantially lower rates of angiographic restenosis and the subsequent need for repeat revascularization (Fig. 8–2).[15-17] Although there is no evidence of reduction in the rates of death and MI, these studies have not been powered sufficiently to examine such particular outcomes. The reduction in major adverse cardiac events in the DES trials can be attributed entirely to reduction in repeat target lesion revascularizations.

It has also been recognized that certain stent designs and characteristics are associated with improved clinical outcomes. These include slotted tube stents versus coil stents,[18] second generation stents,[19,20] and stents with thinner struts.[21,22] Newer stent designs have been developed in the hope that they will further reduce restenosis rates. These include thin strut stents that use the non-bioabsorbable polymer phosphorylcholine to release the sirolimus analog ABT-578, stents with a highly deliverable cobalt-chromium metal alloy platform,[23] and biodegradable stents which provide the scaffolding to prevent abrupt vessel closure in the acute phase and then gradually disintegrate.[24]

Concern has been expressed that the relatively short clinical and angiographic follow-up in most DES trials of 6 to 12 months may be too short for delayed progression of neointimal hyperplasia to become apparent.[25,26] Thus far, long-term



No. at Risk

Sirolimus stent	533	529	527	524	520	515	509	505	493	477
Standard stent	525	523	521	514	506	481	474	465	451	436

Figure 8–2 Actuarial rate of survival free from target-vessel failure among patients who received either a sirolimus-eluting stent or a standard stent. The rate of event-free survival was significantly higher in the sirolimus-stent group than in the standard-stent group ($P < 0.001$ by the Wilcoxon and log-rank tests). (Adapted from Moses JW, Leon MB, Popma JJ, et al: Sirolimus-eluting stents versus standard stents in patients with stenosis in a native coronary artery. N Engl J Med 2003;349:1315-23, with permission.)

follow-up data from observational studies of sirolimus-eluting stents do not suggest a late "catch-up" in neointimal hyperplasia.[27,28] Low rates of target lesion revascularization and of other major adverse cardiac events up to 3 years after device implantation were found in the RAVEL trial.[29] Rates of major adverse cardiac events at 3 years were 15.8% in patients randomly assigned to sirolimus-eluting stents versus 33.1% in patients assigned to BMS ($P = 0.002$).

As with most new technology, trials performed to assess safety and efficacy enroll only a small proportion of the entire universe of patients with CAD that would be potentially eligible for DES. Multi-lesion PCI with DES was not included in any trial. Patients with a recent MI or a low EF were also excluded. Lesion length and reference vessel diameter of the treated vessels usually reflect low-risk discrete lesions in medium-caliber vessels. On the basis of these variables, the patients enrolled in the DES trials have had a low risk of angiographic restenosis in general.[17] (See Chapters 6 and 7 for further discussion).

RELATIVE BENEFITS OF PCI AND CABG

Considerable controversy has existed and continues to exist regarding the relative benefits of PCI versus CABG. Up to 15 randomized trials comparing PCI, with or without stents, and CABG have been published and were reviewed extensively by both Eagle and colleagues[30] and Hoffman and associates.[31] In summary, these trials have shown that CABG tends to give better relief of angina with less need for repeat procedures than does PCI. However, initial costs are lower with PCI, complications occur less frequently, and patients are able to return to work earlier. Because of the greater need for reinterventions, PCI patients generate similar costs over the long term. Long-term survival tends to be similar with the two forms of treatment, except for diabetic patients for whom CABG is the superior treatment. In the meta-analysis reported by Hoffman,[31] for patients with multivessel disease, CABG provided a survival advantage at 5 to 8 years, and for diabetics, a survival advantage at 4 years (Fig. 8–3). Stents reduced the need for repeat procedures by about 50%.[31] Unfortunately, patients enrolled in such trials are not always representative of the global population of patients with CAD; therefore, the results of such trials are not necessarily applicable to the general population of patients. Indeed, only 5% of screened patients with multivessel disease were enrolled in these trials, and patients with left main coronary artery disease were excluded from such studies.

Registry studies have also provided valuable information regarding the relative benefits of medical therapy, PCI, and CABG, particularly for the global population of patients with CAD. Jones and coworkers[32] reviewed the Duke database of 9263 patients with CAD who underwent PCI (2924 patients), CABG (3890 patients), or medical therapy (2449 patients) only. Patients were followed for a mean of 5.3 years. The anatomical severity of the coronary artery stenoses best defined the survival benefit from CABG and PCI versus medical treatment. All patients with single-vessel disease, except those with ≥95% proximal LAD stenosis, benefited from PCI compared with CABG. All patients with three-vessel disease, and those with two-vessel disease with a ≥95% proximal LAD stenosis, were best treated by CABG (Fig. 8–4). Similar findings were found in a review of 60,000 patients in the New York State PCI and CABG Registry (Fig. 8–5).[33] Patients with three-vessel disease or those with severe proximal LAD stenosis (one- and two-vessel disease) achieved improved survival with CABG when compared with PCI.

When considering revascularization in any particular patient, many factors need to be taken into consideration. These include the patient's age, coronary anatomy, extent of stenoses, technical suitability for either PCI or CABG, comorbidities, left ventricular function, urgency of the procedure, and, to some degree, patient preference. Both PCI and CABG provide good relief of symptoms in most patients who are appropriately selected. These procedures need to be considered complementary, and many patients will undergo both of these techniques of revascularization during their lifetime.

SPECIAL SITUATIONS

Diabetes Mellitus

The prevalence of diabetes mellitus in the United States is increasing rapidly, mirroring the rapid rise in obesity. In 1999, 4.9% of the U.S. population was estimated to be suffering from diabetes mellitus and by 2002, this had increased to 6.3%.[34-36] Of individuals older than 60 years, 18.3% are estimated to be diabetic. These demographic changes are almost certainly related to the aging of the population, sedentary lifestyle, poor diet, and obesity. This alarming increasing incidence of diabetes has important consequences related to CAD and its management, as well as for society as a whole. For type I diabetics, the mortality rate from cardiovascular disease is four times that of the general population[37] and by age 55 years, one third of these patients will have died from CAD.[38]

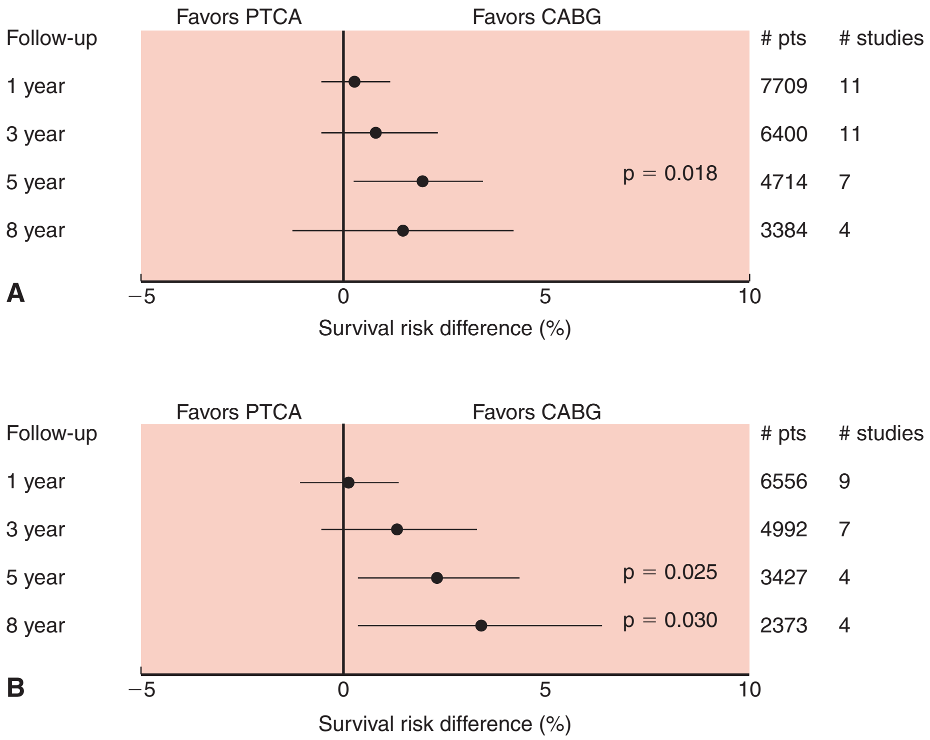


Figure 8–3 Risk difference for all-cause mortality for years 1, 3, 5, and 8 post-initial revascularization. All trials (**A**) and multivessel coronary artery disease (**B**). The *lines* represent 95% confidence intervals. Event rates for the coronary bypass arm at 1, 3, 5, and 8 years for all trials (**A**) were 3.0%, 4.7%, 7.1%, and 13.7%, respectively; for multivessel trials (**B**) event rates were 3.4%, 5.3%, 8.9%, and 15.8%, respectively. CABG, coronary artery bypass graft; PTCA, percutaneous transluminal coronary angioplasty. (Adapted from Hoffman SN, TenBrook JA, Wolf MP, et al: A meta-analysis of randomized controlled trials comparing coronary artery bypass graft with percutaneous transluminal coronary angioplasty: One- to eight-year outcomes. J Am Coll Cardiol 2003;41:1293-1304, with permission.)

For type II diabetics, the incidence of atherosclerosis is estimated to be two to three times that of the general population.[39] The risk of an acute MI is 20% over 7 years, with a hospital mortality rate of 1.5 to 2.0 times higher than that for nondiabetics.[40] Moreover, diabetics who suffer an MI are more likely to develop congestive heart failure, cardiogenic shock, recurrent ischemia, and reinfarction, and poorer survival rate.[41] Thus, diabetes mellitus should be considered a cardiovascular disease as much as an endocrinologic problem, with both macro and micro-angiopathies.

The observed poorer clinical outcomes among diabetic patients with CAD are likely due to multiple factors—coexistent renal disease, hypertension, peripheral vascular disease, and the aggressive nature of the CAD itself. Compared with nondiabetics, diabetics are more likely to have left main disease,[42-46] multivessel disease, diffuse disease with smaller luminal diameters, and a larger number of lipid-rich plaques that are more prone to rupture.[47]

Indications for revascularization in diabetics are generally the same as those for nondiabetic patients. These include symptom improvement, left main disease, triple-vessel disease—particularly with decreased left ventricular function, and severe angina. However, diabetic patients are more likely to be asymptomatic than are nondiabetic patients, with significant myocardial ischemia. In the absence of angina, progression of ischemia with decreased left ventricular function may occur and this, in part, may explain the ultimate poorer prognosis in diabetic patients. In the absence of angina, the Asymptomatic Cardiac Ischemia Pilot (ACIP Study) showed that coronary revascularization was beneficial in selected patients.[48] In patients with known CAD, when therapy was directed by the onset of subsequent angina, the mortality rate at 2 years was 6.6%. Patients revascularized in the absence of angina but guided by the presence of ischemia had a mortality at 2 years of 1.1% (Fig. 8–6). Because of the asymptomatic nature of CAD in diabetics, an aggressive approach should be adopted in these patients to detect myocardial ischemia and to advise subsequent revascularization.

Data from the BARI trial suggest that for diabetic patients with two- and three-vessel disease, long-term survival is superior with CABG in comparison with PCI. In the BARI study,[49] the 5-year survival rate of treated diabetic patients was 73.1% (significantly less than the 91.3% for nondiabetic patients), emphasizing the serious impact that diabetes has on the outcome of patients with CAD, regardless of treatment. Diabetics in the BARI trial were also more likely to be obese, female, hypertensive, and have impaired renal function, peripheral vascular disease, and impaired left ventricular function. At 7 years, the mortality rate for CABG patients was 23.6% and for PCI patients 44.3%.[50] Similar data showing a trend toward improved results with CABG compared with PCI for diabetics were also observed in the Emory Angioplasty

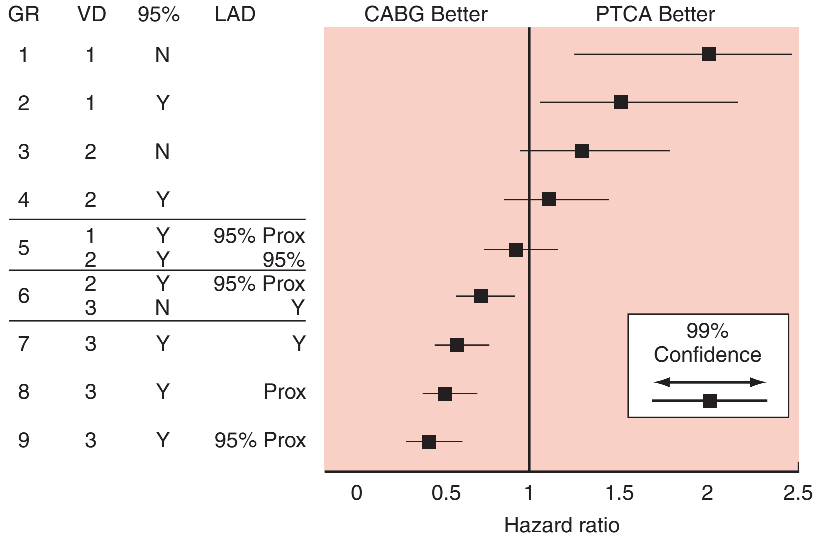

Figure 8–4 Adjusted hazard ratios comparing CABG and PTCA for the nine coronary anatomy groups. versus Surgery Trial (EAST)[51] (8-year mortality rate: CABG 24.5%, PCI 39.9%), and in the Arterial Revascularization Therapy Study (ARTS)[52] (3-year mortality rate: CABG 4.2%, PCI 7.1%). These observations were not reproduced in the BARI registry wherein the mode of revascularization was selected by physician preference.[53] In this registry, sicker and higher risk patients tended to be preferentially referred for CABG, whereas those with lesser degrees of CAD often underwent PCI. During follow-up, diabetic patients in the BARI Registry had equal survival rates when treated either by PCI or CABG.[53]

The improved survival rate seen in diabetics who undergo CABG appears to be contingent on the use of an IMA graft to the LAD coronary artery (7-year survival rate: 83.2% IMA, $n = 140$), whereas long-term survival of patients treated with saphenous vein grafts was similar to those treated with balloon angioplasty (7-year survival rate: 54.5% saphenous vein, $n = 33$).[54] Patients with an IMA graft showed a dramatic reduction in the mortality rate after a subsequent MI compared with patients who did not receive an IMA graft (Fig. 8–7).[54] Further data from BARI indicated that diabetics appeared to have more complete revascularization and less jeopardized myocardium at risk after CABG, compared with diabetic patients who were revascularized with PCI. Diabetic patients also had increased rates of restenosis after PCI compared with nondiabetics, whereas graft patency in those

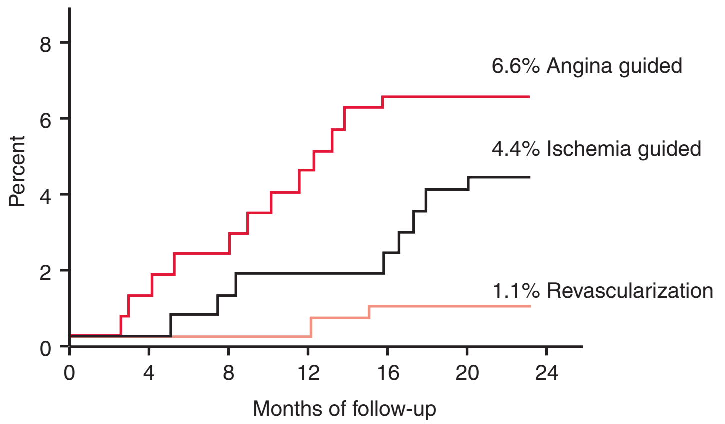

Figure 8–6 Two-year cumulative mortality rates for three treatment strategies. Significant differences were seen between revascularization and angina-guided strategies ($P < 0.005$) and between revascularization and ischemia-guided strategies ($P < 0.05$). Angina-guided and ischemia-guided strategies were not significantly different from each other ($P = 0.34$). The angina-guided strategy consisted of anti-ischemic drug treatment sufficient to control angina. The ischemia-guided strategy added additional active drug therapy if ischemia was still present during AECG recording. Patients in the angina-guided strategy received placebo to maintain blinding. The revascularization strategy consisted of initial treatment with PTCA or CABG aimed at achieving the most complete revascularization possible by the method deemed most appropriate by the physician. AECG, ambulatory electrocardiogram; CABG, coronary artery bypass graft; PTCA, percutaneous transluminal coronary angioplasty. (Adapted from Davies RF, Goldberg AD, Forman S, et al: Asymptomatic Cardiac Ischemia Pilot [ACIP] study two-year follow-up: Outcomes of patients randomized to initial strategies of medical therapy versus revascularization. Circulation 1997;95:2037-43, with permission.)

undergoing CABG (venous and arterial) was not influenced by diabetic status.[55] These data suggest that the survival advantage of CABG in diabetics may be related to a more complete and more durable revascularization than that achieved by PCI. Current trials in the diabetic population with CAD are focusing on earlier revascularization and the use of insulin-sensitizing agents (BARI 2D)[56] and outcomes with DES in comparison with CABG (FREEDOM).[57]

Operative mortality and morbidity after CABG are increased in diabetics compared with nondiabetics, particularly insulin-dependent diabetics.[58] In a review of 41,663 diabetic patients registered in the STS Database, 30-day mortality rates in non-diabetic and insulin-dependent diabetics were 2.5% and 4.6%, respectively. Stroke, renal failure, and infective complications were also higher in insulin-dependent diabetics (Table 8–1).

Unstable Angina and Non-ST-Elevation Myocardial Infarction

Urgent coronary angiography with a view toward revascularization is now the preferred approach to the management of patients presenting with unstable angina and non-ST-elevation myocardial infarction (UA/NSTEMI). Although a number of theoretical advantages exist for an invasive approach, such as the establishment of a definitive diagnosis and triage to definitive therapy, the advantages of such an approach have only been recently verified with the reports of several contemporary trials.

Technological advances in PCI, including the use of stents and glycoprotein IIb/IIIa inhibitors, have facilitated this approach to the ACS. Data from the Mayo Clinic[59] confirmed the improving results of PCI for the management of unstable angina from the early days of coronary angioplasty to the late 1990s. In a population-based analysis of patients presenting with ACS in Olmsted County, Minnesota, between 1985 and 1992, the performance of early coronary angiography within 7 days of presentation was associated with a 37% risk reduction in mortality.[60] Three trials—FRISC-II, TACTICS-TIMI 18, and RITA-III—have also directly addressed the benefits of an early invasive strategy.[61-63]

Despite the clear demonstration of clinical superiority with the invasive approach, in the "real world" the proportion of patients with UA/NSTEMI who receive an early aggressive approach remains low. An analysis of 248 U.S. hospitals enrolled in the CRUSADE registry[64] showed that only 45% of nearly 18,000 patients with UA/NSTEMI had coronary angiography within 48 hours of presentation. Observed in-hospital mortality was significantly lower among patients with active early coronary angiography, in particular those at high risk as defined by a prospective risk score. In conclusion, the early invasive approach for management of UA/NSTEMI is preferred because it confers better clinical outcome—provided the resources exist to render rapid access to high-quality hospitals and experienced operators. The greatest benefit is seen in high-risk patients as characterized by those with positive biomarkers, electrocardiographic changes, and diabetes mellitus.

Primary PCI or CABG for STEMI

Perhaps the clinical subset in which percutaneous revascularization has had such a dramatic impact is in the treatment of ST-elevation myocardial infarction (STEMI).[65,66] Primary PCI (PPCI) is the preferred reperfusion therapy for STEMI. This statement, however, assumes that rapid diagnosis and triage to an experienced catheterization laboratory and team can be achieved. PPCI holds a number of theoretical advantages over lytic therapy for reperfusion, including the ability to visualize coronary artery anatomy and left ventricular function directly, and to provide direct mechanical reperfusion. Patients who

are best treated with medical therapy (e.g., mild disease or resolved thrombotic occlusion) or with surgical therapy (e.g., left main or extensive triple-vessel disease) can also be rapidly identified and triaged to the most appropriate therapy. Supportive measures and adjunctive imaging techniques, such as endotracheal intubation, intra-aortic balloon pumping and echocardiography, are immediately available in most therapeutic catheterization laboratories.

Although the widespread use of fibrinolysis and PPCI has largely superseded CABG for acute reperfusion of patients with STEMI, CABG still plays an integral role in the early reperfusion strategy for a small proportion of patients.[30,65,67] In the PAMI (Primary Angioplasty in Myocardial Infarction)-2 trial,[71] of 1100 patients with STEMI and without cardiogenic shock, 5% underwent CABG as the primary reperfusion strategy for STEMI. Mortality was 6.4% if surgery was undertaken on an urgent or emergency basis versus 2.0% if elective. Major risk factors for death included poor LV function and advanced age.

CABG early after STEMI may carry substantial risk, particularly in unstable patients with Q-wave infarction and decreased LV function. In these circumstances, the timing of such surgery may be important in determining ultimate outcome. Unfortunately, there are no clear guidelines as to when surgery should be undertaken.[65,68-71] In reviewing 11 retrospective and prospective observational studies regarding CABG and STEMI, Crossman and colleagues[71] concluded that timing of surgery after infarction was not necessarily an independent predictor of outcome. However, these studies did "appear to support an approach of medical stabilization for post-STEMI wherever possible to convert high-risk emergency operations to lower risk more elective procedures".[71] If stable patients with STEMI have preserved LV function and require surgical revascularization, then CABG can be undertaken within several days of infarction without an increased risk. In addition, for patients who have mechanical complications of STEMI (ventricular septal rupture or papillary muscle rupture), or who have ongoing ischemia that has been unresponsive to other medical therapy and have vessels suitable for bypass, surgery should be performed without undue delay.[65]

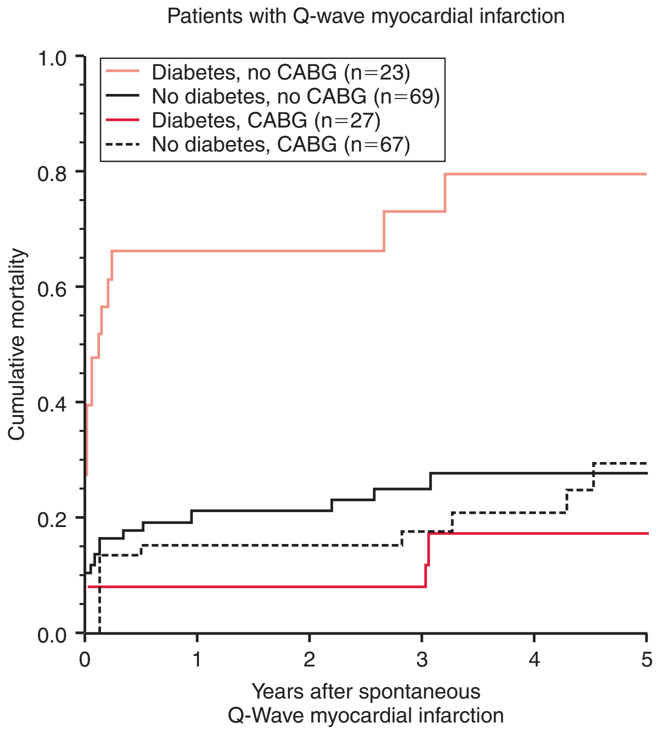

Figure 8–7 Mortality after the initial revascularization procedure. Kaplan-Meier estimates of the cumulative mortality in patients with spontaneous Q-wave myocardial infarction according to diabetes status and CABG status are shown (the numbers in parentheses refer to the 186 spontaneous Q-wave myocardial infarctions that occurred in 176 patients). Patients who did not undergo CABG were treated only with percutaneous transluminal coronary angioplasty. CABG, coronary artery bypass graft. (Adapted from Detre K, Lombardero MS, Brooks MM, et al: The effects of previous coronary-artery bypass surgery on the prognosis of patients with diabetes who have acute myocardial infarction. N Engl J Med 2000;342:989-97, with permission.)

CABG, coronary artery bypass graft; MI, myocardial infarction; UTI, urinary tract infection. Modified from Carson JL, Scholz PM, Chen AY, et al: Diabetes mellitus increases short-term mortality and morbidity in patients undergoing coronary artery bypass graft surgery. J Am Coll Cardiol 2002;40:418-23, with permission.

Patients who have had a significant decrease in LV function as a result of a STEMI and who are hemodynamically stable may benefit from a longer period of medical treatment to allow myocardial recovery to occur before surgical revascularization is undertaken. If a patient has critical coronary anatomy, such as >75% left main coronary artery stenosis, then CABG should be undertaken during the same hospitalization.[30,65]

Less-Invasive CABG

Before 1995, CABG had traditionally been performed with a sternotomy, full cardiopulmonary bypass, and cardioplegic arrest. However, a number of surgeons, particularly Benetti[72] from Argentina and Buffolo[73] from Brazil, gained extensive experience with CABG without cardiopulmonary bypass. This experience stimulated a renewed interest in minimally invasive CABG during the mid-1990s.

The MID-CAB (minimally invasive direct coronary artery bypass) is performed through a left anterior thoracotomy without cardiopulmonary bypass and is generally limited to bypass of the LAD coronary artery using the left IMA. Advantages of the MID-CAB included avoidance of cardiopulmonary bypass and its complications, reduction of operative and hospital costs, early discharge from the hospital, and a possible reduction in postoperative pain. Early anastomotic patency rates, however, were inferior to those treated with conventional CABG with cardiopulmonary bypass, and revascularization was usually limited to the LAD or diagonal coronary arteries. For these reasons, and because few patients with single vessel disease are currently referred for surgical revascularization, the MID-CAB failed to gain extensive use despite a wave of initial enthusiasm.

This initial interest in less invasive CABG led to further refinements in surgical techniques and instrumentation to allow bypass of multiple vessels in all three major coronary territories. Stabilization devices, coronary shunts, and better surgical approaches and techniques for cardiac positioning and improvements in anesthesia have promoted greater use of CABG without cardiopulmonary bypass or off-pump CABG (OP-CAB).[74-80] The advantages of OP-CAB surgery remain controversial, and there are wide variations in its use between surgical groups. It is well recognized that cardiopulmonary bypass may result in significant hematologic, metabolic, pulmonic, cardiac, renal, and neurologic complications, and it was hoped that OP-CAB would prevent these adverse sequelae. Most reports of OP-CAB surgery demonstrate a reduction in transfusion needs, shorter intensive care unit and hospital stays, and reduction in hospital costs.[83-84] There are no firm data indicating a definite reduction in neurological events in OP-CAB cases compared with CABG with cardiopulmonary bypass.

A number of randomized trials have also evaluated OP-CAB and CABG with cardiopulmonary bypass.[74,75,77,78] In a small randomized study of 281 patients by Van Dijk and coworkers,[77,78] the 30-day incidence of stroke was not significantly different in the conventional CABG group compared with the OP-CAB group (1.4% versus 0.7%). In reviewing the STS database, Cleveland and associates[79] reported on 11,717 (9.9%) OP-CAB patients and 106,423 (90.1%) cardiopulmonary bypass patients. The OP-CAB patients were older and had more dialysis-dependent renal failure and cerebrovascular disease than did the cardiopulmonary bypass patients. Emergency surgery and extensive triple-vessel CAD were more prevalent in the cardiopulmonary bypass group. The risk-adjusted mortality rate in the OP-CAB group was 2.31% and in the cardiopulmonary bypass group 2.93% ($P < 0.001$). The OP-CAB patients also had fewer strokes (1.25% versus 1.99%, $P < 0.001$), less renal failure, and less need for re-exploration for bleeding.

Initial experience with the OP-CAB procedures has been mainly related to low-risk patients with single- or double-vessel disease. Experience has shown, however, that patients most likely to benefit from this technique are those who would be at a high risk for complications of cardiopulmonary bypass.[79] These include elderly patients with cerebral, renal, or pulmonary disease or patients with significant calcification of the ascending aorta where cannulation or cross-clamping poses considerable neurologic risk. Small, diffusely diseased, or calcified coronary arteries or intramyocardial vessels make OP-CAB less attractive. The decision to perform an OP-CAB procedure will depend on a number of factors including age, associated comorbidities, size of the native coronary arteries, urgency of the procedure, and, above all, surgeon experience. OP-CAB surgery is more demanding than conventional CABG, and patients with unstable hemodynamics are better served by CABG that uses conventional cardiopulmonary bypass techniques. If the surgeon thinks that the patient will be harmed by an OP-CAB technique, then the operation should be abandoned and converted to a standard cardiopulmonary bypass procedure.

Concern exists regarding the long-term outcome of the OP-CAB procedure, particularly with regard to long-term patency of grafts, recurrence of angina, and the need for further interventions. Arom and associates[80] reported OP-CAB patients to have a higher risk of recurrent angina at 1 year when compared with patients having on-pump procedures. Sabik and coworkers.[81] also reported incomplete revascularization in OP-CAB patients. An American Heart Association (AHA) scientific statement, comparing on-pump with OP-CAB surgery, concluded that patients in general have excellent results with either type of procedure and that individual outcomes depended more on patient intrinsic factors rather than the type of procedure that was performed (Table 8–2).[82] At this time, CABG, using conventional cardiopulmonary bypass techniques, still remains the standard for surgical myocardial revascularization.

Endoscopic Vein Harvesting

A major advance in the minimally invasive approach to CABG is endoscopic saphenous vein harvesting. In the past, leg wound complications such as hematoma, cellulitis, and fat necrosis were common and represented a significant cause of morbidity in patients. This has been a particular problem in obese and diabetic patients. Endoscopic saphenous vein harvesting requires a 3-cm incision above the knee to identify the saphenous vein, followed by CO_2 insufflation of the tissues to follow the course of the vein, dissect and divide its branches, and finally remove the vein at the saphenofemoral junction (Fig. 8–8). Wound complications, time to ambulation, and hospital stays are significantly less with this technique and have produced improvement in patient satisfaction.[83,84] Histologic, electron microscopic, and endothelial cell analyses have demonstrated no differences between the two

Table 8–2 Findings Favoring OP-CAB or On-Pump CABG

Findings Favoring OP-CAB	Findings Favoring On-Pump CABG
Probably less bleeding	Less technically demanding
Probably less renal dysfunction	Shorter "learning curve"
Probably less short-term neurocognitive dysfunction, especially if aorta is calcified	Possibly better long-term graft patency
Possibly shorter overall length of hospital stay	Easier to graft posterior (circumflex) bypass targets
	Probably more bypass grafts constructed

CABG, coronary artery bypass graft; OP-CAB, on-pump coronary bypass. From Sellke FW, DiMaio JM, Caplan LR, et al: Comparing on-pump and off-pump coronary artery bypass grafting: Numerous studies but few conclusions: A scientific statement from the American Heart Association council on cardiovascular surgery and anesthesia in collaboration with the interdisciplinary working group on quality of care and outcomes research. techniques.[85] In this era, endoscopic vein harvesting should be considered the standard of care for most patients.

Minimally Invasive PCI

With improvements in technology, particularly stents and adjunctive pharmacologic therapy, success rates for elective and emergency PCI now approach 96% to 98%, and major procedural complications such as death, MI, or need for emergency CABG occur with frequencies of <1% each. Thus, the majority of procedural complications that occur now relate to the arterial access site. The femoral artery remains the preferred access site for the majority of interventional cardiologists and is susceptible to hemorrhage, hematoma, pseudoaneurysm, arteriovenous fistula formation, and retroperitoneal hemorrhage. The incidence of these complications is directly related to the severity of the underlying vascular disease, particularly in elderly and diabetic patients, as well as to sheath size and anticoagulant use. The availability of miniaturized equipment capable of being delivered through 6-Fr and even 5-Fr sheaths has mitigated the problem. Similarly, the realization that prolonged postprocedural heparin infusions are not necessary has contributed to a dramatic decline in the incidence of vascular complications after PCI. Such complications, however, still occur in 5% to 8% of patients after PCI.

A proposed solution to the problem has been to use the radial artery in preference to the femoral artery as an access site for invasive coronary procedures. Developed and popularized by the efforts of Campeau[86] and Keimineij,[87] transradial coronary angiography has gained popularity in Europe and selected U.S. and Canadian sites. The radial artery can accommodate 5-Fr to 7-Fr sheaths, allowing passage of standard caliber (majority 6 Fr) catheters to the heart for performance of diagnostic and therapeutic procedures. All procedures that can be performed from the femoral artery through 6-Fr guiding catheters may be performed from the radial artery through similar catheters. Because the artery is superficial, has no major adjoining neurovascular structures, and is easily compressible for achievement of hemostasis, the incidence of vascular complications is <1% in experienced hands. Bed rest is not necessary following transradial coronary angiography and this leads to superior patient comfort and satisfaction, and allows for the possibility of true outpatient PCI. Because of its small size, however, cannulation is not always successful and a proportion (generally <5% in experienced hands) of procedures will need to be converted to the femoral approach.

Robotic Surgery

Efforts have been undertaken to perform CABG by total endoscopic techniques.[88-90] Robotic-assisted surgery is performed by a surgeon sitting at a console and viewing the interior of the chest and surface of the heart with 3-dimensional vision. This is accomplished by using cameras that are precisely controlled using foot pedals. The computer-enhanced system filters out physiological tremor that arises from the surgeon's hands and allows precise movement of the robotic instruments. The endoscopic arms are equipped with microsurgical instruments with unlimited range of motion. It is hoped that these closed-chest video-assisted procedures will result in reduced surgical trauma, less pain, decreased bleeding and risk of infection, shorter hospital stays, and more expeditious resumption of normal activities compared with conventional CABG. Initial experience has been limited almost entirely to grafting the LAD and/or the diagonal coronary artery.[90] Many obstacles remain regarding implementation of total endoscopic robotic surgery. These include development of adequate stabilizers and sutureless anastomotic devices, and the extreme cost associated with robotic technology. Total endoscopic CABG is an extremely demanding procedure, and its technical difficulties and cost will need to be addressed before it becomes a standard procedure for both patients and surgeons.

In PCI, remote control of the catheters and wires has now become possible using the Stereotaxis magnetic guidance system. This technology uses two large (approximately 4000 lbs. each) permanent magnets on either side of the patient's body to establish a magnetic field surrounding the heart. The north-south dipole of the field can be manipulated using computer software, and, in combination with 3-dimensional reconstruction of coronary or cardiac anatomy, the operator can precisely steer magnetically enabled wires and catheters. Potential applications of the technology include facilitating PCI in tortuous or occluded vessels, placing biventricular pacing leads, or facilitating ablative electrophysiological procedures.[91]

Total Arterial Grafting

By the early 1980s it was apparent that the long-term patency of the saphenous vein was inferior to that of the IMA (sometimes referred to as the internal thoracic artery [ITA]). Saphenous vein grafts in the first 1 to 2 years may develop intimal hyperplasia and are later subject to vein atherosclerosis (Fig. 8–9). The patency of vein grafts at 5 years is 70% to 80% and at 10 years 40% to 50%. This compares with a 10-year patency rate for IMA grafts of >90%. In 1986, Loop and colleagues[92] demonstrated improved survival at 10 years in patients receiving IMA grafts compared with those receiving saphenous vein (93.4% versus 88%, $P = 0.05$ with two-vessel disease and 82.6% versus 71.0% $P < 0.001$ with three-vessel disease). Patients who received IMA grafts also had fewer subsequent cardiac events and less need for reoperations. The relative scarcity of smooth muscle cells in the thin-walled media of the IMA, combined with a well-formed internal elastic lamina even at advanced age, may be an important reason for its low susceptibility to atherosclerosis and a major determinant to its superior long-term patency as a coronary artery bypass graft.[93]

For patients requiring a graft to the LAD, the use of the IMA is the standard of care in almost all patients, including the elderly. In an analysis of more than 500,000 patients who underwent elective CABG in the United States between 1996 and 1999, the IMA graft was used in 94% of patients younger than 55 years of age and 77% of patients greater than 75 years of age.[2]

Surgeons may be reluctant to use the IMA in certain patients, particularly after STEMI, because of limited flow through the artery or graft and the time necessary to harvest it. In the PAMI-2 trial,[67] of 120 patients undergoing surgery, only 31% received an IMA graft; no patients had cardiogenic shock at the time of surgery. Data suggest that IMA grafts can be used safely soon after STEMI with no increase in mortality.[30,65] Moreover, their use is associated with better long-term survival. Hirose and associates[94] used arterial grafts in 96% of 47 patients undergoing emergency CABG within a mean of 27 hours from infarction, and the operative mortality rate was 6.4%. In a further study, Hirotani and coworkers[95] performed CABG on 98 patients within 30 days of infarction with a mortality rate of 7.4%. CABG without arterial grafts was the sole predictor of an adverse survival.

Because of the clear advantage of single IMA grafting, surgeons have promoted the use of other arterial grafts (right internal mammary, gastroepiploic) together with the concept of total arterial revascularization. Several authors[96-100] have shown increased survival in patients undergoing bilateral IMA grafts. Lytle and associates[100] published long-term results of bilateral versus single IMA grafts involving 1152 propensity matched pairs of patients with a mean follow-up of 16.5 years. Patient survival rates for the bilateral IMA and single IMA groups at 7, 10, 15, and 20 years were 89% versus 87%, 81% versus 78%, 67% versus 58%, and 50% versus 37%, respectively ($P < 0.0001$). As can be seen in Figure 8–10, divergence of the hazard function curves continued to widen, with an increased risk of death with single IMA grafting compared with bilateral IMA grafting through the 20 postoperative years of follow-up. Buxton and colleagues.[96] demonstrated a 10-year patient survival rate for bilateral IMA grafts of 86% compared with 71% for single IMA grafts. For patients younger than 60 years with a normal EF and no significant comorbidity, however, there was no difference in the survival rate. Most benefit was seen in patients older than 60 years with an EF < 35% and with diabetes mellitus (Fig. 8–11).

Concern exists regarding the increased incidence of sternal infection with the use of both IMA grafts (Matsa[97]—2.6%; Tector[98]—3%, Lev-Ran[101]—4%). Because the IMA is an important source of blood supply to the sternum, the use of

both IMAs for grafting may have a serious effect on sternal blood supply and its subsequent healing. Attempts to minimize these effects have used techniques to skeletonize the IMA during harvesting, thereby minimizing the adverse effect of conventional IMA harvesting wherein the taking of a wide pedicle decreases sternal blood supply.[97] In this technique, the IMA is dissected free from all surrounding tissues, including the accompanying veins, fascia, lymphatics and adipose tissue, thus preserving the microvasculature in the surrounding tissues of the chest wall and sternum.

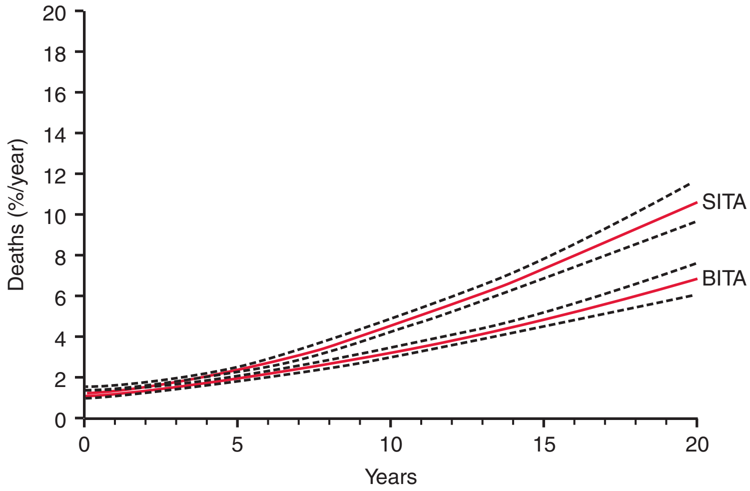

Figure 8–10 Hazard function curves demonstrate the increased risk of death associated with single internal thoracic artery (SITA) grafting with increasing follow-up interval. *Dashed lines* are 68% confidence bands. BITA, bilateral internal thoracic artery. (Note: The abbreviation ITA referring to the internal thoracic artery is synonymous with IMA, which stands for internal mammary artery.) Figure 8–12 Kaplan-Meier curves of cumulative patency rates according to type of bypass graft. Radial artery grafts were associated with worst patency rate of all graft types. Four left internal mammary arteries (LIMA), two right internal mammary arteries (RIMA), five saphenous vein grafts (SVG), and six radial grafts were not included in this curve. (Adapted from Khot UN, Friedman DT, Pettersson G, et al: Radial artery bypass grafts have an increased occurrence of angiographically severe stenosis and occlusion compared with left internal mammary arteries and saphenous vein grafts. Curculation 2004;109:2086-91, with permission.)

There has also been renewed interest in using the radial artery as a conduit for CABG. Although the initial long-term patency of this vessel was poor when used by Carpentier in 1973,[102] better techniques of harvesting the radial artery, as well as the use of long-acting nitrates and/or calcium channel blockers to prevent spasm postoperatively, have improved outcomes. For patients in whom bilateral IMA harvesting may lead to a significant risk of sternal infection, use of a radial artery is a good alternative to a second IMA and can be used in most patients. Contraindications to its use include a positive Allen test, Dupuytren disease, and vascular disease of the upper limb. Ruengsakulrach and coworkers[103] found that the radial artery, when compared with the IMA, had a significantly greater incidence of intimal hyperplasia (94% versus 69%,) atherosclerosis (5.0% versus 0.7%), and medial calcification (13.3% versus 0%). They urged caution in its use in the elderly, diabetics, smokers, and patients with peripheral vascular disease.

Several studies have suggested better patency of the radial artery compared with the patency of the saphenous vein but not as good as that for the IMA. At 1 year, Tatoulis and associates[104] reported a radial artery patency rate of 91%. In a multicenter study, Desai and coworkers[105] randomized 561 patients to receive either a radial artery graft or a saphenous vein graft to a second coronary territory. Radial artery grafts were associated with a lower rate of graft occlusion at 1 year than were saphenous vein grafts. Because the patency of radial artery grafts depended on the severity of native vessel stenosis, such grafts should preferentially be used for target vessels with high-grade lesions.[109] Subsequently Khot and coworkers[106] from the Cleveland Clinic reviewed patency of grafts in patients who were restudied after CABG because of angina (60%) or an abnormal stress test (32%). Radial artery grafts had a patency of 51%, which was inferior to that of the IMA (90%) and saphenous vein (64%) (Fig. 8–12). Patency for women was worse than that for men (39% versus 56%). Further studies are warranted to determine the long-term fate of radial artery grafts before their routine use can be recommended, particularly for women.

Other techniques used to extend arterial grafting include sequential IMA grafting and composite grafting using one IMA or radial artery as a free graft anastomosed to the site of a second IMA pedicled graft (Fig. 8–13).[107] Factors to consider before deciding to use bilateral IMA grafts or other arterial conduits include patient age, diabetic status, urgency of the case, and presence of significant obesity. For example, a 75-year-old morbidly obese diabetic female should not undergo bilateral IMA grafting because of the subsequent risk of serious life-threatening sternal wound infection.

Coronary Revascularization (PTCA or CABG) and Noncardiac Surgery

Coronary revascularization is frequently performed to mitigate the potential risks of major noncardiac surgery. For example, diabetic patients with combined coronary and peripheral vascular disease represent an especially high-risk segment in whom the risks of postoperative MI, arrhythmias, and death are significantly higher than in the general population, especially if functional tests show prior MI or provocable ischemia. The universal availability of noninvasive testing and the attention to preoperative risk assessment has resulted in a substantial number of patients being referred for coronary angiography before major noncardiac surgery. Such patients frequently undergo PTCA, PCI, or CABG before elective noncardiac surgery. A report from Kaluza and coworkers[108] drew attention to an observed catastrophic outcome of noncardiac surgery that is performed too soon after coronary artery stenting. They reported on 40 patients who underwent noncardiac surgery within 6 weeks of coronary stenting with BMS. Of this group, 7 MIs, 11 major hemorrhages, and 8 deaths were reported, with the greatest risk observed within 14 days of the coronary procedure. A subsequent report[109] highlighted the risk of DES thrombosis occurring when all antiplatelet therapy, both clopidogrel and aspirin, was withdrawn to allow noncardiac surgery or endoscopic procedures, such as bladder or colon polyp removal, to be undertaken. Subacute thrombosis in this situation can be associated with a mortality rate approaching 50% and a nonfatal MI rate approaching 40%. Factors likely to contribute to postoperative stent thrombosis include withdrawal of antiplatelet therapy, incomplete endothelialization of stents coated with antiproliferative agents, and the prothrombotic metabolic milieu which occurs after major noncardiac surgery.

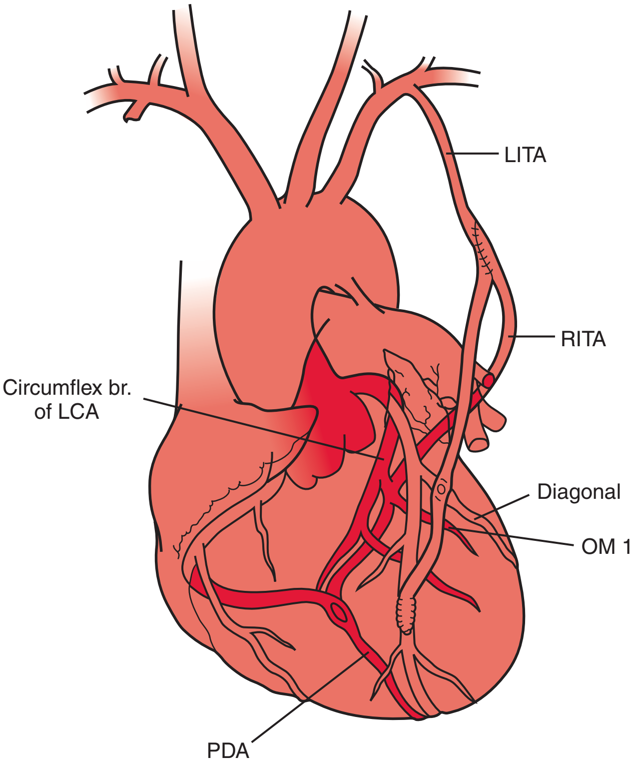

Figure 8–13 Total arterial revascularization using a pedicled left internal thoracic artery (LITA) graft to the left anterior descending (LAD) artery and diagonal and a free right internal thoracic artery graft (RITA) anastomosed proximally to the LITA and distally to the first obtuse marginal (OM 1) and to the posterior descending artery (PDA). Note: the LITA is sometimes referred to as the LIMA.

The development of ACS following the withdrawal of aspirin in patients with CAD has been reported[110] and essentially manifests as an acute STEMI. Both BMS and DES are susceptible to such a complication, although DES may be more vulnerable. Postoperative stent thrombosis can be extremely difficult to treat, with the attendant risks of inducing operative-field bleeding. One suggested approach is to categorize patients according to the competing risks of bleeding following noncardiac surgery and thrombosis of a coronary artery stent. Continuation of antiplatelet drugs should be considered if at all possible, and less invasive alternatives to noncardiac surgery, such as endovascular approaches to treatment of peripheral vascular disease, should be considered.

Earlier CABG, Hybrid Procedures, and Supported PCI

Despite an initial wave of enthusiasm, hybrid CABG and PCI procedures have not become commonly accepted.[111] Used primarily to refer to an off-pump, minimally invasive LIMA to LAD anastomosis (i.e., MID-CAB) in combination with stenting of other vessels either on the same day or at another time, the so-called hybrid procedure suffers major logistical problems. Patients need to undergo two separate procedures, often being subjected to hospitalization and separate sets of risks twice. Moreover, the subsequent less-than-ideal results of the MID-CAB approach to the LIMA to LAD anastomosis have dampened enthusiasm for this procedure, and it is not performed routinely.

Improved procedural outcomes and secondary prevention measures have led to a growing population of elderly patients with prior CABG, previous MI, severe left ventricular dysfunction and angina pectoris secondary to graft occlusion or disease progression. As patients continue to live longer after surgery, patients with patent left IMA grafts and occluded vein grafts are commonly encountered in clinical practice. In such patients, the risks of repeat CABG surgery are significantly greater than the risks of either primary CABG or PCI. Percutaneous interventional techniques on saphenous vein grafts are also associated with a higher incidence of periprocedural MI and death. Distal protection devices, either balloon occluders or filters, have been developed and can lower the risks of distal embolization in such circumstances. However, no good therapy to halt or retard the progression of vein graft disease exists. Statin and aspirin therapies are helpful but often not in the advanced stages of vein graft disease.

Comorbidities such as diabetes mellitus, peripheral and cerebral vascular disease, chronic renal disease, and hypertension are also common. Such patients frequently will have prohibitively high risks with standard repeat CABG or PCI. We have advocated a hybrid approach to such patients, whereby hemodynamic support is employed with either a surgically or percutaneously placed circulatory assist device, of which a number are available. The procedure is generally performed with the assistance of an experienced cardiac anesthesiologist who administers a general anesthetic with endotracheal intubation and central hemodynamic monitoring. The cardiac surgeon or interventionalist experienced in such techniques supervises the hemodynamic support with the circulatory assist device. In such a controlled situation, percutaneous techniques using rotational atherectomy and PCI can be performed with a measure of safety and assurance not achievable with either standard CABG or PCI.

Pre- and Postprocedural Care

Advances in periprocedural care have resulted in improved short- and long-term outcomes for patients who undergo CABG. Preoperatively, most of these improvements relate to optimization of blood glucose control and treatment of hyperlipidemia on admission to the hospital or on diagnosis of CAD. Several authors[112,113] have demonstrated improved outcomes for patients undergoing CABG who have been treated with HMG-CoA reductase inhibitors preoperatively. Pan and associates,[112] in reviewing a propensity-matched cohort of 1362 patients undergoing CABG, found that preoperative HMG-CoA reductase inhibitor use was independently associated with a significant reduction in the composite endpoint of 30-day mortality and stroke (7.1% versus 4.6%). Likewise, in a prospective randomized study, Christenson[113] demonstrated that 4 weeks of treatment with simvastatin (20 mg daily) prior to CABG resulted in a lower incidence of graft stenoses and subsequent interventions at 2 years compared with a group of patients who did not receive simvastatin.

For patients undergoing PCI, effective antiplatelet and antithrombin therapies are necessary during the pre-, intra-, and postprocedural care. Dual oral antiplatelet therapy with aspirin and clopidogrel is now the standard of care. In the preprocedural setting, patients presenting with ACS are treated

Table 8–3 Insulin Infusion Rates According to Blood Glucose Levels

Blood or Plasma Glucose (mg/dL)	IV Infusion Rate (mL/hr)	Insulin Infusion Rate (units/hr)
>400	16	8
350-400	12	6
301-350	8	4
250-300	6	3
200-249	5	2.5
150-199	4	2
120-149	3	1.5
100-119	2	1
70-99	0	0
<70	0	0

The standard algorithm is designed for an average 70-kg patient and may require modification for patients who are substantially larger or smaller. The standard IV insulin solution is 250 units of human regular insulin in 500 mL of 0.45% sodium chloride. Glucose goals should be defined for each patient. In the acutely ill patient or during the immediate perioperative period, a glucose range from 100 to 200 mg/dL is a reasonable goal. Reflectance meter glucose should be measured hourly until the glucose levels have stabilized in the goal range (100 to 200 mg/dL) for 4 hours. Frequency of testing may then be decreased to every 2 hours, and if the glucose control remains stable, to every 4 hours. The algorithm may be progressively increased by 50% increments for each glucose range ≥200 mg/dL if glucose does not decrease into goal range. Hypoglycemic risk is increased if the algorithm is increased for glucose <200 mg/dL.

with an antithrombin and a parenteral glycoprotein IIb/IIIa inhibitor (indicated for high-risk patients with diabetes mellitus, positive biomarkers, or electrocardiographic changes). During the procedure, oral antiplatelet therapy is continued and is frequently supplemented by a glycoprotein IIb/IIIa inhibitor to achieve 80% suppression of platelet activity. Antithrombin therapy is necessary but may be discontinued on completion of the procedure. Following the procedure, dual antiplatelet therapy is continued for a minimum of 1 month (elective BMS) to at least 1 year (DES for ACS). Attention to secondary preventive measures is mandatory for all patients undergoing PCI to minimize the risk of disease progression and the development of nonfatal MI or sudden death.

More widespread use of antiplatelet agents (aspirin) before surgical revascularization has also resulted in an improved patient outcome. In a study from the Mayo Clinic, Bybee and colleagues[114] showed that patients treated with aspirin within 7 days before CABG had a decreased incidence of subsequent death as well as cerebrovascular complications. There was no increased risk of returning to the operating room for bleeding, although transfusion requirements were higher in patients treated with aspirin. We believe that aspirin (81 mg to 325 mg) should be either commenced or continued in patients before surgery, particularly in those with ACS or unstable angina. Preoperative administration of clopidogrel is associated with a significant increase in postoperative hemorrhage and should be stopped, if practical, 5 to 7 days before CABG.[30,65,115] In a prospective study of 224 patients having CABG, Hongo and associates[116] found reoperation for bleeding to be 10-fold higher in patients who had received clopidogrel within 7 days of surgery than in those who had not received clopidogrel.

Several reports have emphasized the importance of maintaining normoglycemia in the surgical patient. Gandhi and coworkers[117] from the Mayo Clinic demonstrated that elevated intraoperative glucose levels during cardiopulmonary bypass were significantly associated with an increased mortality, and more frequent pulmonary and renal complications. Studies also suggest that improved outcomes in patients undergoing CABG can be achieved with better glucose control and the use of glucose, insulin, and potassium infusions during surgery. Lazar and colleagues[118] showed that patients who received a glucose/insulin/potassium infusion perioperatively had a significantly lower incidence of atrial fibrillation, a shorter postoperative stay, a survival advantage, and decreased episodes of myocardial ischemia and wound infection over the subsequent 2 years. Similar findings related to infection were also recorded by Furnary and associates.[119] Management of perioperative hyperglycemia should be undertaken with an appropriate algorithm, adjusting intravenous insulin infusion rates according to blood glucose levels. A suggested algorithm is presented in Table 8–3.

CURRENT APPROACHES TO REVASCULARIZATION DECISIONS

In Figure 8–14, we present an integrated and comprehensive approach to making revascularization decisions in the current era. As mentioned in the introduction to this chapter, there are three broad indications for coronary revascularization (1) relief of symptoms and improvement in quality of life; (2) improvement of long-term prognosis (i.e., reduction in the risk of premature death); and (3) prevention of nonfatal events such as MI, congestive heart failure and/or ventricular arrhythmias. It should be recognized that although both PCI and CABG are highly effective in relieving symptoms, only CABG has been definitively shown to improve prognosis in stable CAD, and even then only for the highest risk of anatomical subsets of patients such as those with left main CAD or severe triple-vessel disease, particularly with decreased left ventricular function. Neither procedure has been shown to

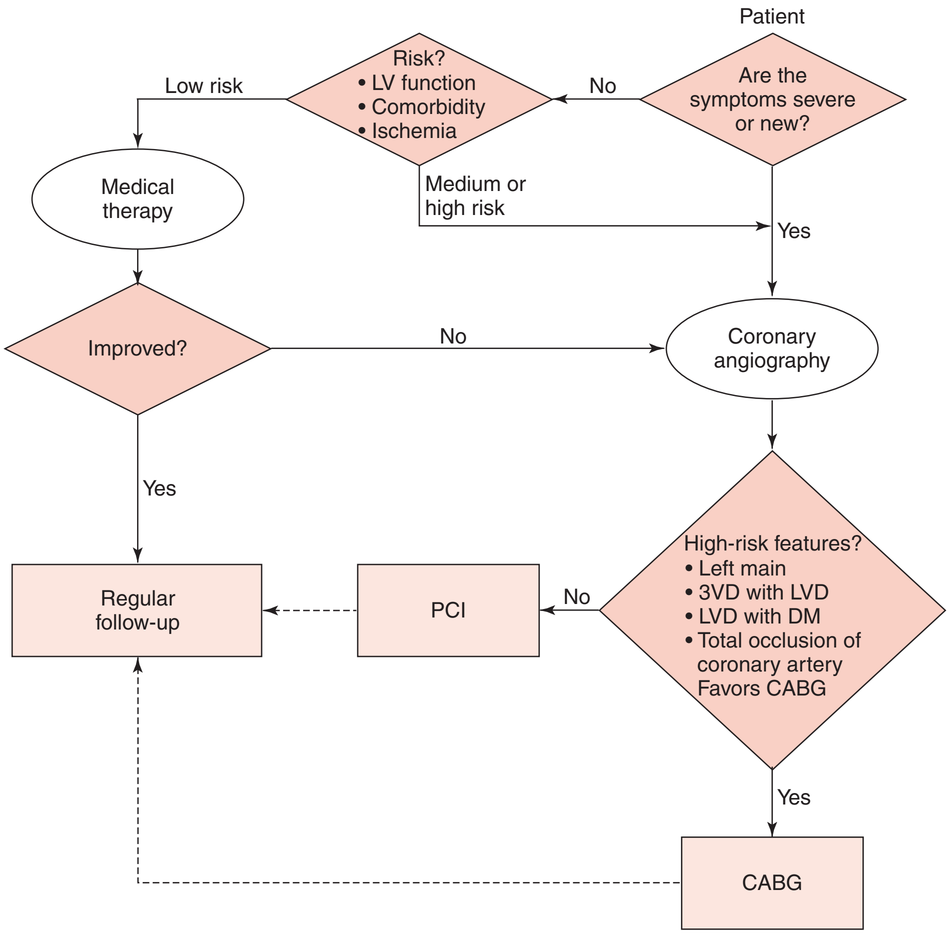

Figure 8–14 A risk-based approach to the management of patients with suspected coronary artery disease. Central to this approach is the ability to develop an estimate of cardiovascular risk based on standard clinical criteria including age, left ventricular function, extent of myocardial ischemia, and medical comorbidities. Low risk can be defined as an estimated annual mortality of <1%, medium risk 1% to 5%, high risk >5%. Various clinical risk scores are available that incorporate clinical and functional information. In general, patients with normal left ventricular function and mild ischemia in the territory of only one coronary artery will have a low annual risk. Regular follow-up entails implementation of aggressive secondary preventive efforts and periodic surveillance for recurrent symptoms or ischemia. CABG, coronary artery bypass graft; DM, diabetes mellitus; LVD, left ventricular dysfunction; 3VD, three-vessel disease; PCI, percutaneous coronary intervention;. (Adapted from Gibbons RJ, Abrams J, Chatterjee K, et al: ACC/AHA 2002 guideline update for the management of patients with chronic stable angina—Summary article: A report of the ACC/AHA Task Force on Practice Guidelines. J Am Coll Cardiol 2003;41:159-68 and Miller TD, Roger VL, Hodge DO, Gibbons RJ: A simple clinical score accurately predicts outcome in a community-based population undergoing stress testing. Am J Med 2005;118:866-72, with permission.)

prevent MI, likely caused by the initial risk of periprocedural myocardial necrosis. In acute presentations, only PCI has been validated in randomized trials for the treatment of UA/NSTEMI.

Revascularization decisions are perhaps most straightforward in acute presentations of ischemic heart disease, whereby patients presenting with UA/NSTEMI should be triaged to hospitals with angiography facilities and undergo early (generally within 24 to 72 hours) coronary angiography.[65,115] Patients presenting with STEMI who can undergo PCI in a timely fashion by skilled operators should undergo immediate coronary angiography with a view to percutaneous revascularization and reperfusion of the infarct-related artery.[65] Should left main CAD or severe multivessel disease be encountered, then subsequent revascularization can be individualized based on each patient's circumstances.[30]

In chronic ischemic heart disease, the situation is more complex, and a rigorous review of the indications and goals of revascularization with the patient and his or her family is necessary. For example, most elderly patients will require revascularization procedures for improvement of quality of life, and long-term prognosis, although important, may be a lesser concern. A younger patient may require revascularization for improving prognosis even in the absence of significant symptoms. These indications should be clearly discussed with the patient before undertaking any revascularization procedure, and the patient's expectations of the effectiveness of the procedure should also be carefully reviewed (e.g., many deconditioned patients may not experience a marked improvement in exercise tolerance or energy unless they are also willing to undertake lifestyle modifications in conjunction with the revascularization procedure).

To allow selection of the most appropriate revascularization method, a detailed assessment of coronary artery anatomy and regional and global left ventricular function is mandatory. Coronary angiography in an accredited and quality-controlled laboratory, possibly supplemented with intravascular ultrasound or coronary physiological measurements, is required for precise anatomic delineation of the degree and extent of CAD. Particular attention to left main coronary artery involvement, the presence or absence of chronic total occlusions, or other complex anatomical subsets such as bifurcation lesions, osteal lesions, and calcified lesions is required. Left ventricular function is the most important determinant of acute and long-term prognosis after revascularization, and either noninvasive or invasive assessments of left ventricular function in conjunction with coronary artery anatomy are necessary. These measures will often have been supplemented by noninvasive assessment of myocardial ischemia, either by perfusion scan or direct visualization with echocardiography. Thus, a comprehensive evaluation of the patient as a candidate for revascularization includes an assessment of symptoms, myocardial ischemia, left ventricular function, and coronary artery anatomy.

In addition to these cardiac factors, a thorough assessment of systemic comorbidities that influence both short- and long-term risks is also needed. In particular, the presence of cerebrovascular disease, diabetes mellitus, peripheral vascular disease, and chronic renal disease all significantly increase the risk of periprocedural complications, as well as portend a poorer long-term prognosis. The next step in patient evaluation requires a technical evaluation of the various modes of revascularization that can be offered. Factors such as the presence of complex lesions or poor distal vessels may influence the selection of one modality versus the other. For example, an unapproachable chronic total occlusion may tilt the balance in favor of complete revascularization with surgery. In general, complete revascularization in chronic CAD is preferable and is associated with improved long-term outcome. Alternatively, the presence of diffuse disease and poor distal vessels with poor outflow may portend a high incidence of periprocedural graft closure and poor prognosis after CABG. A discussion between an experienced interventional cardiologist and cardiovascular surgeon, often in conjunction with the patient's referring physician and family members, will usually lead to the most informed decision-making in these complex circumstances.

The short-term risk of periprocedural complications needs to be balanced against the relative long-term benefits. Because of the greater intensity and more invasive nature of CABG surgery, patients on the one hand frequently are at risk for more periprocedural complications and longer hospital stays with associated costs; on the other hand, complete revascularization and long-term results may be superior in some patient subsets. Ultimately, these considerations need to be carefully weighed in the selection of the revascularization procedure. Patient preference needs to be taken into account because patients will frequently select a less invasive alternative as initial treatment, thereby reserving the more invasive option for a future date. As surgical and interventional techniques along with the associated medical therapy improve, it is increasingly apparent that the techniques are not competitive but in most instances are complementary and that weighing of the foregoing factors will lead to the best decision-making for each patient encountered in clinical practice

LONG-TERM SECONDARY PREVENTION

Patients recovering in the hospital after CABG or PCI are in an ideal environment to initiate secondary prevention measures. Because of the emotional trauma associated with hospitalization and revascularization, patients and families are very receptive to educational measures directed at secondary prevention. There is also evidence that these initiatives, begun in the hospital, are more likely to be followed after discharge.[120] Moreover, the medical advantages of antiplatelet therapy as well as lipid reduction before invasive procedures in hospital are considerable. The American Heart Association has initiated a program called "Get with the Guidelines" to encourage in-hospital initiation of secondary prevention measures for all patients who have CAD.[121] The American College of Cardiology has also promoted the "Guidelines Applied in Practice" (GAP) program to assist cardiologists and others to improve quality and efficiency of care by giving them practical tools that encourage implementation of guidelines at the point of care.[122] Similar initiatives have also been undertaken by the Society of Thoracic Surgeons as part of its quality improvement program.[2]

Aspirin

All patients with CAD should receive aspirin (81mg to 162 mg) indefinitely.[123] This can be commenced within 6 hours of CABG and may be given through a nasogastric tube if the patient is not yet extubated. Mangano and colleagues[124] studied 5022 patients in a global registry who survived CABG. Aspirin therapy begun within 48 hours after surgery resulted in a 60% lower death rate at 30 days, as well as decreased rates of MI, stroke, renal failure, and bowel infarction. It is likely that these effects are mediated by both the anti-inflammatory and antithrombotic actions of aspirin.[125] Bleeding complications were also lower in the aspirin-treated group. The most appropriate dose of aspirin is not known. However, the lower dose of aspirin (81 mg) will have fewer side effects and is most probably equally as effective as higher doses.

Cholesterol Reduction

The need to reduce serum lipids in patients with CAD is well accepted. There are accumulating data that statins may also have a beneficial effect on bypass grafts in preventing or slowing the development of graft atherosclerosis and that these benefits may be independent of the starting and resulting LDL-C levels.[126-129] In the Post Coronary Artery Bypass Graft (Post CABG) Trial, aggressive lowering of LDL cholesterol to 60 to 85 mg/dL with lovastatin (up to 80 mg daily) resulted in a significant reduction in graft atherosclerosis and occlusion compared with the group of patients who had only moderate reduction of LDL cholesterol (130 to 140 mg/dL).[127] The early phase of the trial lacked statistical power to study clinical events. There was, however, a 29% reduction in revascularization procedures in the aggressively treated group compared with the moderately treated group. In

a longer term follow-up of 7.5 years, cardiovascular mortality rates and the rate of nonfatal MI or stroke were reduced by 24% in the aggressively treated group (P = 0.001).[128] In the CARE (Cholesterol and Recurrent Events) trial, patients who had a documented MI were randomized to treatment with either placebo or pravastatin.[129] In those patients who were revascularized, treatment with pravastatin led to significant reduction in fatal and nonfatal MI, repeat revascularization, and stroke. These effects were seen in both PCI and CABG patients.

Almost all patients who have undergone PCI and/or CABG should be discharged from the hospital on a HMG-CoA reductase inhibitor (statin) therapy unless their LDL-C level is <70 mg/dL with nonpharmacological treatment. Although the optimal level of LDL-C for patients who have CAD and who have undergone revascularization (either PCI and/or CABG) is not known, other benefits of statins may include their anti-inflammatory and antithrombotic effects.[126] Lipid levels and AST assays should be rechecked in 6 weeks after commencing statins.

β-Blockers

Trials have demonstrated significant reduction in mortality (23% at 5 years) in patients treated long term with β-blockers after MI.[130] Because 50% to 60% of patients undergoing revascularization have had a previous MI, the majority of these patients should be treated with a β-blocker postoperatively. In addition, β-blockers are useful in treating postoperative atrial fibrillation as well as hypertension. Preferred β-blockers include metoprolol or carvedilol.

ACE Inhibitors

A number of trials that randomized more than 100,000 patients have shown a clear benefit of angiotensin-converting enzyme (ACE) inhibitors in patients with CAD and impaired left ventricular function.[131] We recommend ACE inhibitors, if possible, for all patients who have undergone CABG and/or PCI and who have an EF of <40%. Because of issues of postural hypotension in the early postoperative period when combining ACE inhibitors with a β-blocker, use of these medications may need to be individualized depending on clinical circumstances (e.g., need to control atrial fibrillation, poor left ventricular function, recent MI, diabetes). Nevertheless, high-risk patients should be discharged, if possible, on ACE inhibitors as well as β-blockers.

Lifestyle Changes

All patients should be counseled regarding smoking cessation, diet, and exercise. Patients who continue to smoke after CABG have a greater risk of death and repeat revascularization compared with patients who quit smoking.[131,132] At 5 years, the survival benefit for those who have stopped smoking may be as high as 14%.[133,134] Patients are encouraged to enroll in a cardiac rehabilitation program based on exercise training, smoking cessation, diet, lipid management, psychosocial management, and occupational assessment. Programs based on exercise therapy have been shown to reduce subsequent cardiac morbidity and mortality over the ensuing 5 to 10 years.[135]

Primary Prevention of Ischemic Heart Disease

Judith Meadows, Jacqueline Suk Danik, and Michelle A. Albert

CHAPTER CONTENTS

Cardiovascular disease (CVD) is the leading cause of death worldwide resulting in more than 17 million deaths.[1] In the United States alone, coronary artery disease affects more than 12 million Americans.[2] Over the last 3 decades, the mortality from CVD has declined progressively in all race/ethnic and gender groups, a trend that has begun to level off (Fig. 9–1).[3,4] Advances in the detection and treatment of CVD have resulted in the noted decline and longer life expectancy enjoyed by many in the developed world. Primary prevention focusing on identification and treatment of hyperlipidemia and hypertension, as well as the use of aspirin, have contributed considerably to improvements in outcome.

However, significant challenges remain in combating the CVD crisis—including the differences in morbidity and mortality by race/ethnic group; gender and socioeconomic status; the burgeoning obesity epidemic in the developed as well as in many parts of the developing world; the need to better identify and treat persons to reach current guideline goals; and the continuing escalating cost of care. Risk communication and physician and public understanding of and compliance with recommended treatment guidelines are other major challenges in reducing coronary heart disease (CHD), morbidity, and mortality. For example, because CHD scoring algorithms generally do not take into account an individual's relative risk of CHD compared with others in his or her age category, an individual who is 35 years of age who might be at moderate to high risk for CHD for his or her age category could miss the opportunity for primary prevention because he or she is considered to have a low 10-year absolute risk of CHD—resulting in physicians not adequately being able to communicate risk.[5]

RISK DETERMINATION

The most critical step toward decreasing CVD burden involves early identification, monitoring, and treatment of at-risk individuals. The goal of primary prevention is to prevent the development of disease in an asymptomatic person via the early identification and treatment of risk factors for cardiovascular disease. However, an essential step in the latter involves adequate risk assessment. *Absolute risk* of CVD is the risk of developing CVD during a given period of time (typically a period of 10 years), whereas *attributable risk* refers to the difference in the incidence of CVD between person(s) who have been exposed and have not been exposed to a cardiovascular risk factor(s). Traditionally, risk stratification for CHD has used algorithms such as the Framingham Cardiovascular Risk Score (Fig. 9–2)[6] and the European Society of Cardiology Coronary Risk Chart (Fig. 9–3).[7] Both scoring systems estimate an individual's absolute 10-year risk of a CHD event based on gender. Traditional risk factors for CHD such as age, smoking status, presence or absence of diabetes, total cholesterol level (or low density cholesterol level) and systolic blood pressure are included in both scoring modules; diastolic blood pressure and high density lipoprotein are included in the Framingham risk equation but not in the European scoring system. Persons who have an absolute risk of CHD greater than 20% are considered high risk and are candidates for intensive risk reduction through behavioral and drug treatment. Intermediate risk defines persons at 10% to 20% absolute risk of CHD, a group in which safe, cost-effective interventions are recommended. Low-risk individuals have less than a 10% absolute 10-year risk of CHD. However, the usefulness of these scoring systems in non-white populations has come under scrutiny particularly in the United States. Additionally, the ascribed categories of low (<10%) and high (>20%) still leaves a large number of intermediate risk individuals who might also benefit from early intervention. It is estimated that intermediate risk comprises 40% of the U.S. population.[8]

The traditional risk factors for CHD comprise both modifiable and nonmodifiable components. Modifiable risk factors

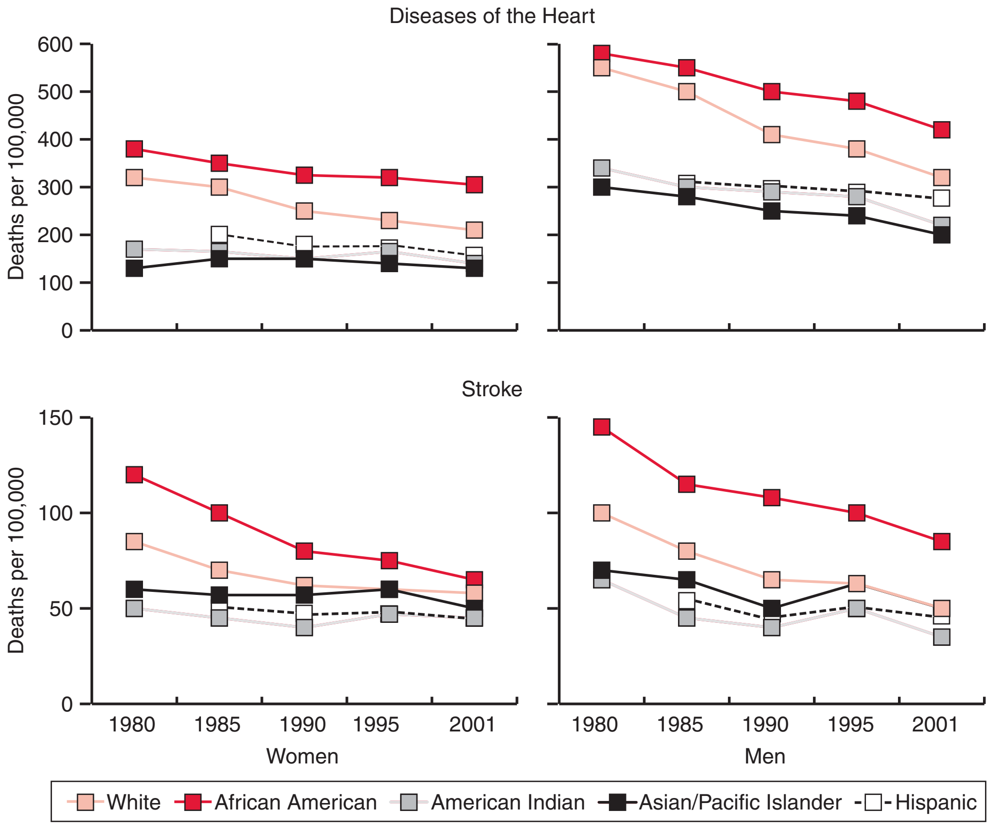

Figure 9–1 Death rates for diseases of the heart and stroke by race/ethnicity and sex in the United States, 1980 to 2001: Age adjusted to the 2000 U.S. population. (From Mensah GA, Mokdad AH, Ford ES, et al: State of disparities in cardiovascular health in the United States. Circulation 2005;111[10]: 1233-1241.)

include dyslipidemia, diabetes, smoking, hypertension, diet, and lack of exercise, whereas nonmodifiable factors include age and family history of CHD. Other factors that contribute significantly to CHD risk include postmenopausal status among women, psychosocial and socioeconomic factors. Over the past few years, debate has ensued regarding the prevalence of conventional risk factors in patients who develop CHD and has led to the proliferation of research related to nontraditional risk factors of CHD.[9,10] Because the pathophysiology of CHD involves the interaction of lipids and inflammation, molecular, hemostatic, and inflammatory markers such as C-reactive protein (CRP), serum amyloid A (SAA), vascular and cellular adhesion molecules, soluble CD40 ligand, fibrinogen, lipoprotein (a), homocysteine, lipoprotein phospholipase A2, and plasminogen activator inhibitor 1 (PAI-1) have emerged as novel risk predictors of CHD.[11,12]

Traditional as well as nontraditional risk indicators of CHD demonstrate a graded CHD risk effect. Much of the evidence to support these relationships has been derived from prospective epidemiologic cohort studies. Besides prospective epidemiologic cohorts, other study designs include cross-sectional, prospective, retrospective cohort, case-control, and randomized clinical trials. Table 9–1 demonstrates a listing of common study designs used in CHD research. Measurement tools to detect subclinical atherosclerosis such as carotid ultrasonography, electron beam computed tomography, and exercise stress testing identify subclinical CHD in clinical trials and population-based cohorts. However, these tests are not incorporated into cardiovascular risk score analyses, and the ability of these tools to determine adequately total vascular disease burden is limited.

DYSLIPIDEMIA

The causal relationship between dyslipidemia and CHD events/mortality has been confirmed in large, randomized controlled trials of primary prevention with HMG Co-A reductase inhibitors.[13-17] A large body of evidence in primary and secondary prevention demonstrates that statin therapy reduced CHD events by 31% and all-cause mortality by 21% (Table 9–2).[18-20] Trials with fibrates and cholestyramine have demonstrated both positive[21,22] and negative[23] results for primary prevention of CHD in patients with hypercholesterolemia.

LDL cholesterol is considered the primary atherogenic factor and is the current focus for primary prevention of CHD.[24] The Lipid Research Clinics Prevalence Study showed that 10-year mortality is associated with high LDL cholesterol in patients with and without CHD.[25] Similarly, several studies have demonstrated that LDL lowering reduces CHD risk and CHD mortality.[26] The West of Scotland Coronary Prevention Study (WOSCOPS) is a large-scale primary prevention study that demonstrated a decrease in CHD events in men with hypercholesterolemia who were administered lipid-lowering therapy to reduce LDL.[17] The greatest benefit of pravastatin therapy was seen in the highest risk group with the number needed to treat of 17 patients over 5 years to prevent one death. The number needed to treat in the low-risk group was 66 individuals for 5 years to prevent one death. The absolute benefit in WOSCOPS for primary prevention was three times lower than that seen for secondary prevention in the 4S trial.[27]

In prospective trials of LDL lowering for primary prevention of CHD, there does not appear to be a lower

Figure 9–2 Coronary heart disease (CHD) score sheet for calculating 10-year CHD risk according to age, total cholesterol (TC) (or low-density lipoprotein cholesterol [LDL-C]), high-density lipoprotein cholesterol (HDL-C), blood pressure, diabetes, and smoking. Use of the LDL-C categories is appropriate when fasting LDL-C measurements are available. Score sheet for men based on the Framingham experience in men 30 to 74 years old at baseline. Average risk estimates are based on typical Framingham subjects, and estimates of idealized risk are based on optimal blood pressure, TC of 160 to 199 mg/dL (or LDL of 100 to 129 mg/dL), HDL-C of 45 mg/dL, no diabetes, and no smoking.

How to Use the Coronary Risk Chart for Primary Prevention

The chart is for estimating coronary heart disease (CHD) risk for individuals who have not developed symptomatic CHD or other atherosclerotic disease. Patients with CHD are already at high risk and require intensive lifestyle intervention and, as necessary, drug therapies to achieve risk factor goals.

- **To estimate a person's absolute 10 year risk of a CHD event,** find the table for their gender, smoking status, and age. Within the table, find the cell nearest to their systolic blood pressure (mm Hg) and total cholesterol (mmol/L or mg/dL).
- **The effect of lifetime exposure to risk factors** can be seen by following the table upwards. This can be used when advising younger people.
- **High-risk individuals** are defined as those whose 10-year CHD risk exceeds 20% or will exceed 20% if projected to age 60.

threshold of LDL below which CHD benefit is lost. The Air Force/Texas Coronary Atherosclerosis Prevention Study (AFCAPS/TexCAPS) was a trial for primary prevention of CHD in patients with low HDL cholesterol (average total cholesterol 221 mg/dL and LDL cholesterol 150 mg/dL) randomized to a low fat/low total cholesterol diet and lovastatin or placebo.[15] Lovastatin was associated with a 37% reduction in CHD events at 5.2 years. The benefit of LDL lowering in primary prevention extended to patients with normal LDL cholesterol levels. In the WOSCOPS, AFCAPS/TexCAPS, the Anglo-Scandinavian Cardiac Outcomes Trial-Lipid Lowering Arm (ASCOT-LLA) trial of hypertensive individuals, and the Collaborative Atorvastatin Diabetes Study (CARDS) trial of diabetics, individuals with multiple cardiac risk factors derived the greatest benefit from lipid reduction.[28,29] Furthermore, angiographic trials report that statin therapy is associated

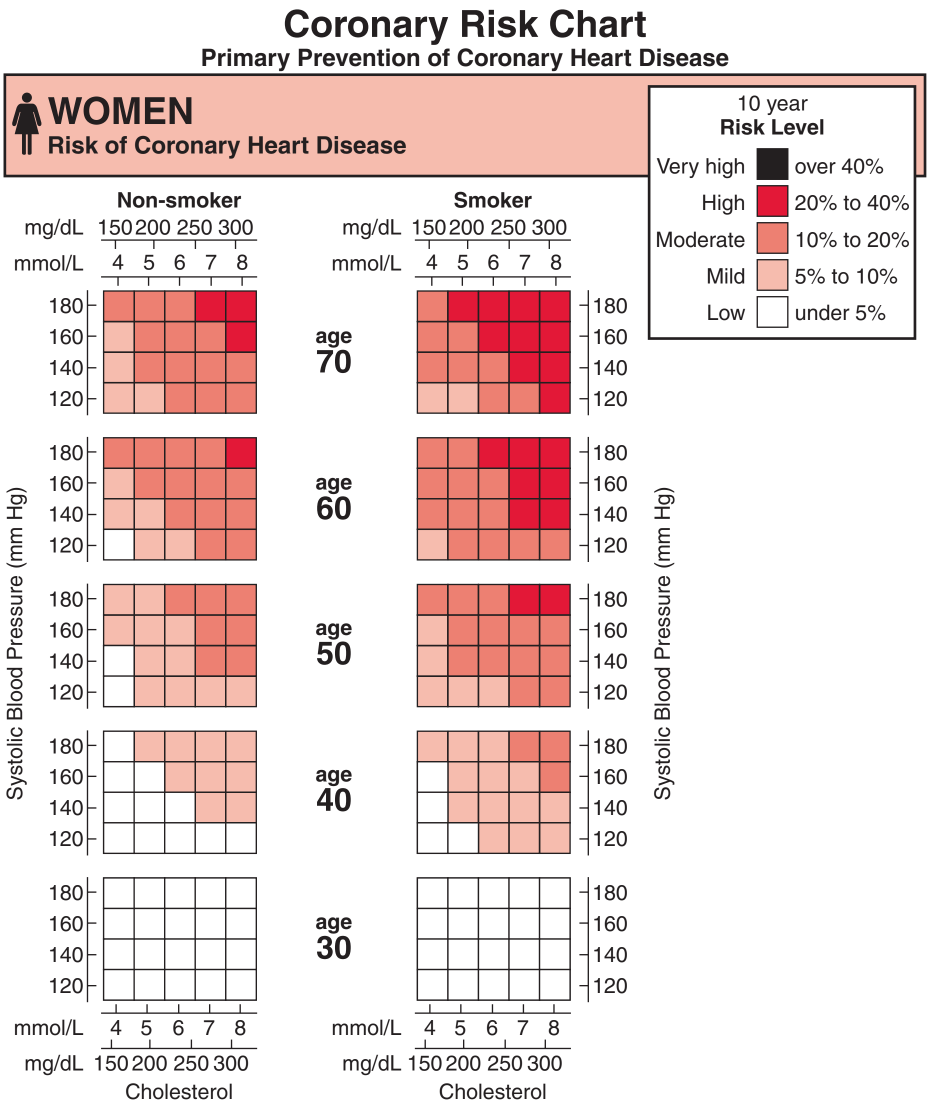

Figure 9–3 *Continued.*

- **CHD risk is higher than indicated in the chart for those with**
  - Familial hyperlipidemia
  - Diabetes: risk is approximately doubled in men and more than doubled in women
  - Those with a family history of premature cardiovascular disease
  - Those with low HDL cholesterol. These tables assume HDL cholesterol to be 1.0 mmol/L (39 mg/dL) in men and 1.1 (43) in women
  - Those with raised triglyceride levels >2.0 mmol/L (>180 mg/dL)
  - As the person approaches the next age category
- **To find a person's relative risk,** compare their risk category with those for other people of the same age. The absolute risk shown here may not apply to all populations, especially those with a low CHD incidence. Relative risk is likely to apply to most populations.
- **The effect of changing cholesterol,** smoking status, or blood pressure can be read from the chart.

B

with retarded progression and regression of atherosclerotic lesions.[30,31] Statins may also provide benefit beyond lesion regression and confer antithrombotic and anti-inflammatory effects.[32]

Optimal LDL cholesterol levels for both men and women are defined by the epidemiological, retrospective, and prospective trials. In the ARIC study, LDL cholesterol levels greater than 118 mg/dL were associated with an age-adjusted increase in CHD of 42% in men and 37% in women.[33] An HDL of 1 SD above the mean (40 mg/dL in men and 51 mg/dL in women) was associated with a 36% decrease in CHD risk among men and a 31% decrease in CHD risk among women. Prediction of CHD risk was not enhanced by HDL subtypes. Also an independent predictor of CHD in women, triglycerides elevated 1 SD above a mean triglyceride of 115 mg/dL was associated with a 31% increase in CHD risk. Additionally,

Table 9–1 Common Study Designs in Coronary Heart Disease Research

Study Type	Goals	Subjects	Advantages	Disadvantages
Experimental				
Randomized clinical trial	To evaluate potential treatment for a disease. To identify a preventive of disease sequelae. To prevent disease in those at risk.	Patients with disease Persons at risk of disease	More equal/balanced distribution of potential confounders Risks and benefits of given exposure/intervention can be evaluated.	Can be expensive
Field trial: Community Intervention Trial Cluster Randomized Field Trial	Intervention implemented on a community-wide basis Treatment assigned randomly to group of participants	Disease-free subjects		Visit subject in the field or subjects come to a central locale Can be expensive when used to study extremely common or serious disease
Nonexperimental				
Cohort study (can be follow-up or incidence study)	To identify and follow a population to evaluate disease	Compares different exposure groups who are initially disease free	Can establish incidence directly. Minimizes recall and other biases that may occur if the outcome is already known. Can assess the relation between an exposure and many diseases.	Many more subjects must be enrolled than will experience the outcome of interest. Expensive, due to high cost of studying many people over long periods of time. Cannot be used to investigate rare diseases. A long time is required for results to emerge.
Case-control study	To determine the contribution of a risk factor within a source population (relative effect measure). To evaluate new risk factors.	Samples according to the outcome of individuals in a population. Controls must be sampled independently of their exposure status.	Efficient Investigates rare diseases	Selection and recall bias
Cross-sectional study	To generate a hypothesis	Subjects represent all persons in a population (or a representative sample) at time of ascertainment. Both exposure and disease are assessed at same time. Includes those with and without disease.		Cannot control for confounding factors. Cannot distinguish whether exposure preceded disease or if disease affected exposure (i.e., current exposure may be unrelated to current disease). Over-represents cases with long duration and under-represents those with short duration of disease.

*On-trial LDL-C values are calculated from published data.
†Results for CABG; the need for PTCA was reduced by 19% (P = 0.024). NNT indicates number needed to treat to prevent one major coronary event (100/absolute risk reduction).
From Maron, Fazio DJ, Linton MF: Circulation 2000;101:207-13.

Lp(a) elevation of 1 SD above the mean of 8.7 mg/dL in men and 11 mg/dL in women was associated with a 15% and 17% increase CHD risk among men and women, respectively. Clustering of multiple CHD risk factors also heightened the risk of CHD.

Screening for Dyslipidemia

Based on findings from large, randomized clinical trials, the National Cholesterol Education Program (NCEP) issued the third Adult Treatment Panel (ATP III) report in 2001 offering guidelines to reduce the incidence of dyslipidemia.[24] NCEP/ATP III recommends that all adults older than 20 years obtain a fasting lipoprotein panel every 5 years. Total cholesterol levels vary by 4% to 11% due to stress, minor illness, and posture.[34] The American College of Physicians recommends screening of men aged 35 to 65 years and women aged 45 to 65 years.[35] In addition, the United States Preventive Services Task Force recommends routine screening of adults between 20 to 35 years if they have other CHD risk factors.[36]

The ATP III guidelines recommend treatment goals based on three CHD risk categories.[24] (Tables 9–3 and 9–4). High risk includes individuals with preexisting CHD or CHD risk equivalents and includes a 10-year CHD mortality of greater than 20%. CHD risk equivalents include peripheral vascular disease, abdominal aortic aneurysm, symptomatic carotid disease, and diabetes mellitus. Individuals with LDL cholesterol greater than 100 mg/dL should initiate therapeutic lifestyle changes. Individuals with LDL cholesterol greater than 130 mg/dL should be placed on lipid-lowering medications.

Treatment Recommendations for Dyslipidemia Categories

High-risk patients with elevated triglycerides or low HDL cholesterol levels also benefit from therapy directed at these specific dyslipidemias. Although ATP III guidelines do not mandate drug therapy when LDL is less than 129 mg/dL, high-risk patients appear to benefit from an LDL cholesterol goal <70 mg/dL. Since the publication of ATP III guidelines, four randomized trials (HPS, PROSPER, ASCOT-LLA, and PROVE IT-TIMI 22) have recommended reduced treatment thresholds for high-risk patients.[29,37-39]

ATP III defines intermediate risk as the presence of two or more CHD risk factors and a 10-year CHD mortality of less than 20%. Intermediate risk patients should achieve a goal LDL cholesterol of less than 130 mg/dL through lifestyle changes. If lifestyle changes fail to achieve LDL lowering to 130 mg/dL or if the initial LDL cholesterol is greater than 160 mg/dL, drug therapy should be initiated. Finally, ATP III defines low risk as one or no risk factors and a 10-year CHD mortality of less than 10%. However, some argue that some individuals in this category may in fact be intermediate risk. The goal LDL for low-risk individuals is less than 160 mg/dL. If the LDL cholesterol remains greater than 190 mg/dL after therapeutic lifestyle changes, LDL lowering medications may be prescribed. An HDL cholesterol greater than 60 mg/dL is considered protective against CHD. Figure 9–4 outlines the treatment algorithms for elevated LDL cholesterol.

NCEP/ATP III offers recommendations for cholesterol reduction with lifestyle/pharmacologic intervention based on individual risk profile and LDL cholesterol level. The first-line strategy is lifestyle intervention (see Fig. 9–4A). Diet should include less than 7% of calories from saturated fat, less than 200 mg cholesterol per day, 55% of daily calories from carbohydrates, 15% of daily calories from protein, 10% of daily calories from polyunsaturated fat, and 20% of daily calories from monounsaturated fat. In addition, patients should pursue weight reduction and physical exercise. If LDL cholesterol goal is not achieved within 6 weeks, plant stanols/sterols and fiber should be added to the diet. Drug therapy should be initiated if LDL goal is not met within another 6 weeks (see Fig. 9–4B). The European Society of

Table 9–3 ATP III Classification of LDL, Total, and HDL Cholesterol (mg/dL)

LDL Cholesterol	
<100	Optimal
100-129	Near or above optimal
130-159	Borderline high
160-169	High
Cigarette smoking	
Hypertension (blood pressure ≥140/90 mm Hg or on antihypertensive medication)	
Low HDL cholesterol (<40 mg/dL)	
Family history of premature CHD (CHD in male first-degree relative <55 years; CHD in female first-degree relative <65 years)	
Age (men ≥45 years; women ≥55 years)	

Diabetes is regarded as a coronary heart disease (CHD) risk equivalent; LDL indicates low-density lipoprotein; HDL, high-density lipoprotein; HDL cholesterol >60 mg/dL counts as a "negative" risk factor; its presence removes a risk factor.
From NCEP/ATP. JAMA 2001;285:2486-2497.

Table 9–4 LDL Cholesterol Goals and Cutpoints for Therapeutic Lifestyle Changes (TLC) and Drug Therapy in Different Risk Categories

Risk Category	LDL Goal (mg/dL)	LDL Level at Which to Initiate Therapeutic Lifestyle Changes (mg/dL)	LDL Level at Which to Consider Drug Therapy (mg/dL)
CHD or CHD risk equivalents (10-year risk >20%)	<100	≥100	≥130 (100-129: drug optional)*
2+ Risk factors (10-year risk ≤20%)	<130	≥130	10-year risk 10%-20%: ≥130 10-year risk <10%: ≥160
0-1 Risk factor†	<160	≥160	≥190 (160-189: LDL-lowering drug optional)

*Some authorities recommend use of LDL-lowering drugs in this category if an LDL cholesterol level of <100 mg/dL cannot be achieved by therapeutic lifestyle changes. Others prefer use of drugs that primarily modify triglycerides and HDL; e.g., nicotinic acid or fibrate. Clinical judgment also may call for differing drug therapy in this subcategory.
†Almost all people with 0-1 risk factor have a 10-year risk <10%; thus, 10-year risk assessment in people with 0-1 risk factor is not necessary. LDL: low-density lipoprotein; CHD, coronary heart disease.
From NCEP/ATP. JAMA 2001;285:2486-2497.

Cardiology (ESC) recommends initial lifestyle modifications for all risk categories before the use of medications.[7]

Although both the NCEP/ATP III and ECS recommend lifestyle changes as first-line therapy, the evidence of CHD benefit is limited. In the United Kingdom Lipid Clinics program, among individuals treated with dietary changes—60% had mean weight reduction of 1.8%, which was associated with a 5% to 7% reduction in total cholesterol and LDL cholesterol.[40] In another study of patients with low HDL and elevated LDL cholesterol who were randomized to exercise, low fat/low cholesterol diet, exercise plus diet, or usual care, those treated with exercise plus low fat/low cholesterol diet had a significant reduction in LDL (14.5±22.2 mg/dL in women, 20.0±17.3 mg/dL in men) compared with other groups. Significant LDL cholesterol reduction was not achieved in the diet alone group.[41]

Despite good evidence of the cardiovascular benefit of cholesterol reduction, the NHANES study described suboptimal awareness, lipid panel screening, and control of dyslipidemia. Only 20% of U.S. adults have had their serum cholesterol evaluated.[42] Of individuals with total cholesterol greater than 200 mg/dL, 69.5% have undergone lipid panel testing; only 35% of this group were aware of their diagnosis and only 12% were treated for elevated cholesterol.[43]

TRIGLYCERIDES AND HDL-C

While total cholesterol and LDL cholesterol are the primary targets of the NCEP/ATP III guidelines, other atherogenic dyslipidemias confer heightened cardiovascular risk. In a meta-analysis of prospective population studies, an 88 mg/dL increase in triglyceride level independently conferred a 14% and 37% increased risk of CHD in men and women, respectively.[44] The increased CHD risk of hypertriglyceridemia is independent of HDL concentration.[45,46]

Low serum HDL, which often accompanies elevated triglycerides, is another important risk factor for CHD. In the Framingham Heart Study, each 5 mg/dL decrease in HDL from median values was associated with a 25% increase in the risk of myocardial infarction.[47] Also, an analysis of four prospective U.S. trials demonstrated that each 1 mg increase in HDL was associated with a 2% decrease in CHD risk among men and a 3% decrease in CHD risk among women.[48] There are no prospective trial data of primary prevention of CHD with fibrates in individuals with low HDL cholesterol, but post-hoc analyses of fibrate trials show reduction in CHD risk, especially among diabetics and those with the metabolic syndrome.[49] The Veterans Affairs High-Density Lipoprotein Cholesterol Intervention Trial Study Group (VA-HIT) assessed

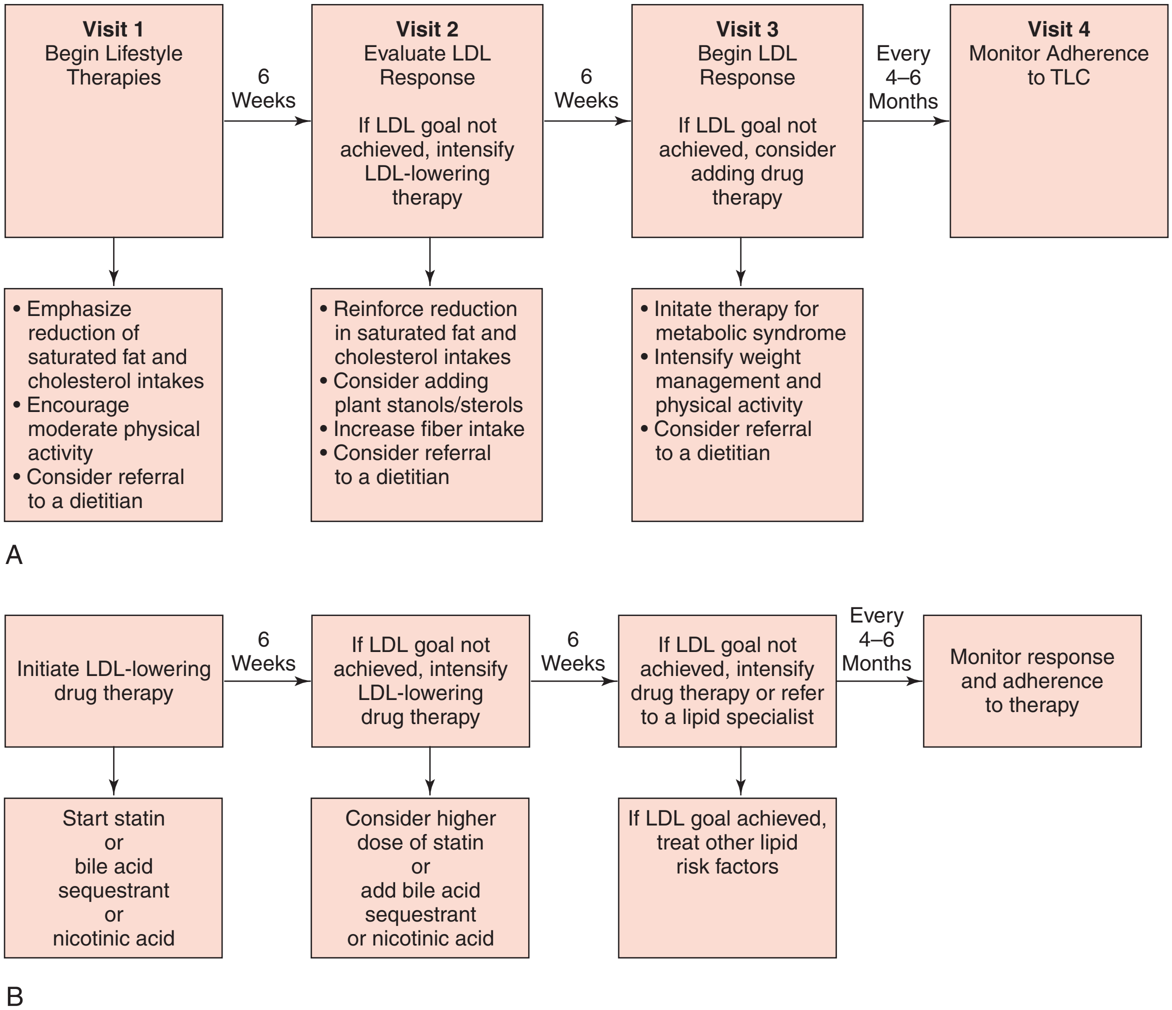

Figure 9–4 **A,** Model of steps in therapeutic lifestyle changes (TLC). **B,** Progression of drug therapy in primary prevention. LDL, low-density lipoprotein. (From Executive Summary of The Third Report of The National Cholesterol Education Program [NCEP] Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults [Adult Treatment Panel III]. JAMA 2001;285:2486-97.)

the role of gemfibrozil in the secondary prevention of CHD in men with CHD and isolated low HDL cholesterol (mean 32 mg/dL). Gemfibrozil was associated with a 7.5% increase in HDL cholesterol and a 22% reduction in CHD death or nonfatal MI.[50] Although all fibrates can be used in combination with statins for management of dyslipidemia, fenofibrate in combination with a statin has not been associated with a substantial increase in myopathy risk.[51] Nicotinic acid has also been shown to increase HDL cholesterol and reduce CHD risk when used alone and in combination with statins.[52]

APOLIPOPROTEINS

Although LDL is the primary target of lipid lowering strategies, some data support the measurement of apolipoprotein-B and LDL particle concentrations. Small LDL particles or small core cholesterol content confer a heightened CHD risk than merely indicated by LDL concentration.[53] In the Familial Atherosclerosis Treatment Study (FATS) and the Women's Health Study (WHS), changes in LDL buoyancy and particle size were important predictors of CHD.[54,55] In diabetic patients, small dense LDL levels had a significant association with CHD progression independent of LDL cholesterol, apolipoprotein B, and triglyceride levels.[56] New measurements of APO-B and APO A-1 assess total number of atherogenic (LDL, VLDL, IDL) and anti-atherogenic particles (HDL), respectively. Some studies have demonstrated that high APO-B and low APO A-1 are important predictors of CHD risk.[33,57,58] The Apolipoprotein-related MOrtality RISk (AMORIS) and the AFCAPS/TexCAPS studies both concluded that APO-B was a stronger predictor of coronary events than was LDL cholesterol.[59,33]

Another lipid target is the total cholesterol/HDL ratio; studies indicate that this ratio has a greater predictive value for CHD than LDL cholesterol or total cholesterol.[60,61] In men, a ratio greater than or equal to 6.4 identified a 2% to 14% greater CHD risk than predicted by total cholesterol or LDL alone. In women, a ratio greater than or equal to 5.6 identified a 25% to 45% greater CHD risk than predicted by total cholesterol or LDL alone. A 1 unit decrease in the total cholesterol/HDL ratio was associated with a 53% reduction in

risk of myocardial infarction. In a comparison of the predictive utility of different lipid measures, total cholesterol/HDL and APO-B/APO A-1 ratios (hazard ratios 3.81 and 3.01, respectively) were more predictive of CHD events than non-HDL cholesterol, LDL cholesterol, APO A-1, or APO-B (hazard ratios 2.51, 1.62, 1.75, and 2.50), respectively.[61a] Measurement of apolipoproteins may not add predictive value to standard lipid measurements given the close association of non-HDL cholesterol with APO-B and total cholesterol/HDL ratio with APO-B/APO A-1 ratio.

HYPERTENSION

According to the WHO, hypertension is the single most preventable cause of death. The JNC VII defines hypertension as systolic blood pressure greater than or equal to 140 mm Hg, diastolic blood pressure as greater than or equal to 90 mm Hg, or use of antihypertensive medications.[62] Hypertension is the most common diagnosis in the United States and accounts for 35 million office visits.

An estimated 60 million Americans are hypertensive. The prevalence of hypertension increases as the population ages. In the Framingham Heart Study, among individuals who were 55 years old, more than 50% developed hypertension within the subsequent 10 years.[63] There are an estimated 2 million individuals diagnosed with hypertension each year,[64-66] and worldwide there are 1 billion hypertensive individuals.

Risk factors for the development of hypertension include advanced age, sedentary lifestyle, body-mass index, excess sodium consumption, low dietary potassium, alcohol use, family history of hypertension, and African-American ancestry.[67] Additionally, population studies demonstrate that the prevalence of hypertension is highest in older individuals, non-Hispanic blacks, and females (Fig. 9–5).[68] The designation of prehypertension (SBP 120 to 139 mm Hg/DBP 80 to 89 mm Hg) implies an increased risk for progression to hypertension.[69] Moreover, normal blood pressure (systolic blood pressure 120 to 129 mm Hg, diastolic blood pressure 80 to 89 mm Hg) confers a two to four times increase in risk of developing hypertension than optimal blood pressure (systolic blood pressure less than 120 mm Hg, diastolic blood pressure less than 80 mm Hg).[70]

Epidemiological studies demonstrate a continuous, consistent, linear relationship between blood pressure and cardiovascular disease that is independent of other cardiac risk factors.[69,71] In the INTERHEART study, hypertension accounted for 18% of the population attributable risk for a first myocardial infarction.[57] In The Prospective Studies Trialists' collaboration, a meta-analysis of more than 1 million individuals without a history of coronary heart disease or stroke, each incremental increase in systolic blood pressure of 20 mm Hg, and diastolic blood pressure of 10 mm Hg resulted in the doubling of CHD risk over a blood pressure range of 115/75 to 185/115 mm Hg (Fig. 9–6).[66]

Hypertensive individuals also have a higher prevalence of other atherogenic risk factors such as dyslipidemia, glucose intolerance, obesity, metabolic syndrome, and left ventricular hypertrophy than do normotensive individuals. The coexistence of cardiac risk factors with hypertension lends an additive effect on the relative risk of CHD.[72] Of public health relevance are data from the Medical Research Council (MRC) trial of mild hypertensives. The number needed to treat to prevent one CHD event was 262 over 5 years, and for persons older than 55 years who smoke and have systolic blood pressures greater than 160 mm Hg, the number needed to treat was four over a period of 5 years to prevent one CHD event.[73]

Randomized clinical trials demonstrate that blood pressure reduction is beneficial in reducing morbidity and mortality related to stroke, coronary heart disease, and heart failure.[74] Treatment of hypertension resulted in a reduction in the incidence of cerebrovascular disease by 35% to 40%, of myocardial infarction by 20% to 25%, and of heart failure by greater than 50%.[75] Treatment of mild-to-moderate hypertension is also critical. A meta-analysis of hypertension treatment trials of 37,000 individuals with mild-to-moderate hypertension revealed that, a decrease in diastolic blood pressure of 5 to 6 mm Hg reduced the incidence of myocardial infarction by 14% and total CVD by 42%.[76] The benefit of hypertension treatment has been demonstrated in both primary and

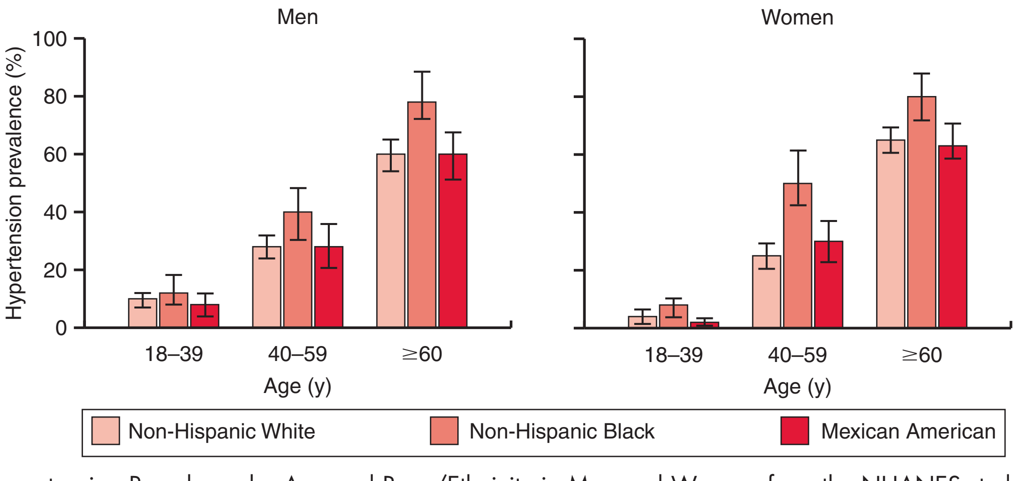

Figure 9–5 Hypertension Prevalence by Age and Race/Ethnicity in Men and Women, from the NHANES study. Error bars indicate 95% confidence intervals. Data are weighted to the U.S. population. (From Hajjar I, Kotchen TA: Trends in prevalence, awareness, treatment, and control of hypertension in the United States, 1988-2000. JAMA 2003;290:199-206.)

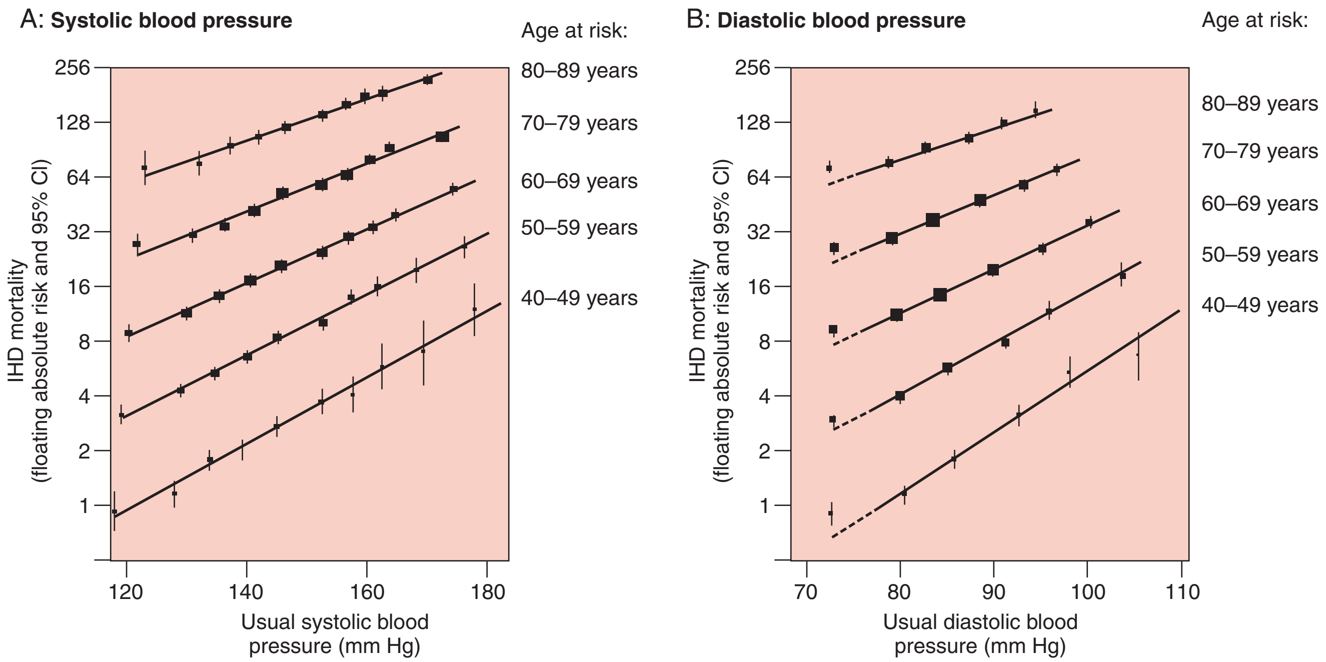

Figure 9–6 Coronary heart disease (CHD) mortality rate in each decade of age versus usual blood pressure at the start of that decade. CHD mortality increases with blood pressure and with age. (From Prospective Studies Collaborative, Lancet 2002;360:1903.)

secondary prevention. For example, for persons with stage 1 hypertension (systolic blood pressure 140 to 159 mm Hg, diastolic blood pressure 90 to 99 mm Hg) and an additional CV risk factor, reduction in SBP of 12 mm Hg over a 10-year period can prevent 1 death for every 11 patients treated.[77] Moreover, clinical trials such as HOPE, EUROPA, and CAMELOT suggest that treatment to reduce blood pressure beyond recommended goals is beneficial in high-risk patients.[78-80]

Hypertension Treatment Recommendations

JNC VII provides guidelines for antihypertensive therapy for adults older than 18 years of age based on blood pressure levels measured as the mean of two or more blood pressure readings on two or more office visits.[62] The prehypertension designation recognizes that the blood pressure–cardiovascular risk relationship extends down to 115/75 mm Hg and that patients with prehypertension are at increased risk for developing hypertension.[70] Unlike JNC VI and the European Society of Hypertension-European Society of Cardiology guidelines, JNC VII does not stratify hypertensive individuals and antihypertensive management by cardiovascular risk factors (Table 9–5). The European guidelines delineate three stages of hypertension plus optimal, normal, and high-normal blood pressure in addition to classifying individuals as low, moderate, high, and very high risk according to their 10-year risk of cardiovascular disease.[81] The European guidelines have less aggressive treatment recommendations than JNC VII. Figure 9–7 shows the treatment algorithm for hypertension based on JNC VII.

Nonpharmacologic Treatment of Hypertension

Nonpharmacologic lifestyle modification is recommended for all patients with prehypertension (120 to 139/80 to 89 mm Hg). Nonpharmacologic strategies include weight loss, dietary changes and salt restriction, exercise, and avoidance of alcohol. Weight loss is effective for blood pressure reduction in both obese and nonobese individuals.[82,83] JNC VII recommends daily consumption of sodium chloride of 6 grams per day or less in normotensive individuals and sodium consumption of 2.4 grams per day or less in hypertensive individuals. Additionally, 30 minutes of moderate intensity exercise three times per week will reduce systolic blood pressure by 5 to 9 mm Hg in both normotensive and hypertensive individuals.[84] Finally, both acute and chronic alcohol use has been shown to increase blood pressure.[85]

Trial Data for Pharmacologic Treatment of Hypertension

Pharmacologic treatment is recommended for persons with a BP greater than or equal to 140/90 mm Hg, except in persons with diabetes or chronic kidney disease wherein treatment should be instituted for BP greater than or equal to 130/80 mm Hg. Although it is cost effective to treat low-risk patients with mild hypertension (140 to 150/90 to 99 mm Hg), JNC VII does not endorse treatment of lower blood pressures because of insufficient clinical trial evidence to support such treatment.[76] Despite appropriate pharmacologic treatment of hypertensive individuals, NHANES and the Western Infirmary in Glasgow data showed that treated hypertensives have a higher mortality than nonhypertensive individuals;

Table 9–5 Classification and Management of Blood Pressure in Individuals Older Than 18 Years

BP Classification	Systolic BP, mm Hg*		Diastolic BP, mm Hg*	Management* Lifestyle Modification	Initial Drug Therapy: Without Compelling Indication	Initial Drug Therapy: With Compelling Indication
Normal	<120	and	<80	Encourage		
Prehypertension	120-139	or	80-89	Yes	No antihypertensive drug indicated	Drug(s) for the compelling indications†
Stage 1 hypertension	140-159	or	90-99	Yes	Thiazide-type diuretics for most; may consider ACE inhibitor, ARB, β-blocker, CCB, or combination	Drug(s) for the compelling indications Other antihypertensive drugs (diuretics, ACE inhibitor, ARB, β-blocker, CCB) as needed
Stage 2 hypertension	≥160	or	≥100	Yes	Two-drug combination for most (usually thiazide-type diuretic and ACE inhibitor or ARB or β-blocker or CCB)‡	Drug(s) for the compelling indications Other antihypertensive drugs (diuretics, ACE inhibitor, ARB, β-blocker, CCB) as needed

ACE, angiotensin-converting enzyme; ARB, angiotensin-receptor blocker; BP, blood pressure; CCB, calcium channel blocker.
*Treatment determined by highest BP category.
†Treat patients with chronic kidney disease or diabetes to BP goal of less than 130/80 mm Hg.
‡Initial combined therapy should be used cautiously in those at risk for orthostatic hypotension.
From Chobanian AV, Bakris GL, Black HR, et al: the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure: The JNC 7 Report, JAMA 2003; 289:2560-71

women have a 30% increased risk, and men have a 36% increased risk of mortality over 9 years.[86]

Clinical trials have shown that blood pressure lowering with multiple drug classes (angiotensin converting enzyme [ACE] inhibitors, angiotensin receptor blockers, β-blockers, calcium channel blockers, thiazide-type diuretics) all reduce the complications of hypertension.[75,80,87-89]

Pharmacologic Treatment of Hypertension

Table 9–6 shows various high-risk conditions associated with hypertension and the recommended drug therapies. ALLHAT and JNC VII recommend thiazide-type diuretics as first-line therapy for blood pressure reduction, given the long clinical experience, clinical trial data, and the cost effectiveness of this regimen.[87] When used in combination with other antihypertensives, diuretics also enhance the efficacy of other antihypertensive agents. Selection of alternative or additional antihypertensive agents should be driven by compelling comorbid conditions and by the severity of hypertension. If initial blood pressure is greater than 20/10 mm Hg above goal, JNC VII recommends initiating two agents. In the ALLHAT trial, less than 30% of participants achieved goal blood pressure of less than 140/90 mm Hg on monotherapy.[87] When initiating multiple BP-lowering agents in patients with orthostatic hypotension, diabetes, autonomic dysfunction, and advanced age, an enhanced schedule of monitoring of the patient is suggested to detect adverse reactions early. β-Blockers are recommended as first-line therapy in CHD. Hypertensive patients with stable angina can be treated with β-blockers or calcium channel blockers.[62] In the context of an acute coronary syndrome, both β-blockers and ACE inhibitors are recommended.[90] In post-MI hypertensive individuals, β-blockers, ACE inhibitors, and aldosterone antagonists are recommended.[62] Hypertension precedes the development of heart failure in 90% of patients and hypertension increases the risk of heart failure twofold in men and threefold in women. Patients with asymptomatic LV dysfunction should be treated with an ACE inhibitor and β-blocker therapy.[91-93] Patients with symptomatic LV dysfunction should also be treated with angiotensin-receptor blockers, aldosterone antagonists, and loop diuretics.[94]

Diabetics with hypertension have a reduced life-expectancy versus nondiabetics with hypertension. In the UKPDS trial, diabetics whose blood pressures were tightly controlled had decreased risks of death, diabetic complications, stroke, and microvascular disease compared with their counterparts who had less tight BP control.[95] Additionally, the Hypertension Optimal Treatment (HOT) study revealed a 50% reduction in cardiovascular events among diabetics with tightly controlled blood pressure (mean DBP 81 mm Hg) compared with those diabetics with less tightly controlled blood pressure (mean DBP 85 mm Hg).[96] Both UKPDS and HOT imply that blood pressure goals should be lower in diabetics and that small differences in blood pressure equate to large differences in clinical outcomes. Therefore, JNC VII recommends that the goal BP in diabetics be less than 130/80 mm Hg. Most patients require two agents to achieve this goal.

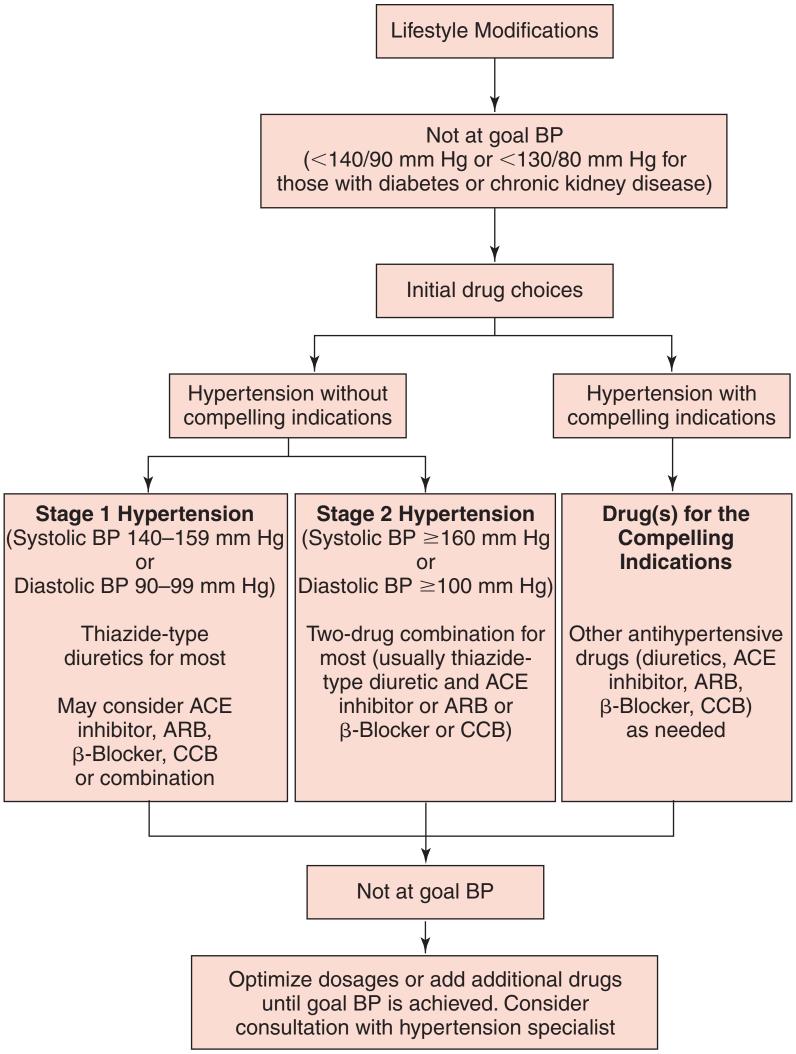

Figure 9–7 Algorithm for the treatment of hypertension: ACE, angiotensin-converting enzyme; ARB, angiotensin-receptor blocker; BP, blood pressure; CCB, calcium channel blocker. (From Chobanian AV, Bakris GL, Black HR, et al: The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure: The JNC 7 report. JAMA 2003;289:2560-71.)

Patients with chronic kidney disease represent another group of patients in whom tight blood pressure control is warranted. Chronic kidney disease is defined as an estimated GFR of less than or equal to 60 mL/min per 1.73 m^2 or a creatinine >1.5 mg/dL in men or >1.3 mg/dL in women. A meta-analysis of randomized controlled trials of patients with nondiabetic kidney disease found that the lowest risk of progression of kidney disease and of CHD was at SBP between 110 to 129 mm Hg.[96] In patients with chronic kidney disease, the goal BP should be less than 130/80 mm Hg. ACE inhibitors and angiotensin receptor blockers have been shown to retard the progression of nondiabetic kidney disease.[97]

Left ventricular hypertrophy (LVH) is an independent risk factor for the development of cardiovascular disease and confers a twofold increased risk of cardiovascular death in men and women.[98] LVH is associated with hypertension, obesity, excess dietary salt, and family history of LVH.[99] Regression of LVH is associated with aggressive blood pressure control due to lifestyle modification and all antihypertensive drug classes, except direct vasodilators.[100,101] Regression of LVH is also associated with cardiovascular risk reduction.[102,103]

Despite the availability of effective antihypertensive therapies, and the clear graded relationship between hypertension and cardiovascular risk, only 30% of hypertensive individuals are aware of their diagnosis and less than one half of these individuals receive adequate treatment.[104] According to JNC VI, rates of blood pressure control are lowest among Mexican-Americans and Native Americans.[105] Black Americans have a higher prevalence of hypertension and its complications than do other race/ethnic groups—a finding that may be related to biologic as well as socio-environmental influences. Studies have shown improved blood pressure lowering with calcium channel blockers and diuretics as opposed to β-blockers and ACE inhibitors in the black population.[87] Although two thirds of the elderly population have hypertension, blood pressure control among the elderly is the lowest among hypertensives owing to underdiagnosis, the presence of comorbidities, and adverse side effects from medications.[104]

SMOKING

According to the CDC National Health Interview Survey, the prevalence of cigarette smoking among U.S. adults is 21.6%.[106] Smoking rates progressively increase with decreasing socio-economic status. The ARIC study demonstrated that tobacco

*Compelling indications for antihypertensive drugs are based on benefits from outcome studies or existing clinical guidelines; the compelling indication is managed in parallel with the blood pressure.

†Conditions for which clinical trials demonstrate benefit of specific classes of antihypertensive drugs.

From Chobanian AV, Bakris GL, Black HR, et al: The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Preassure: The JNC 7 Report JAMA 2003; 289:2560-2571.

caused a 50% increase in the progression of atherosclerosis based on measurements of carotid intimal-medial thickness.[107] Epidemiological studies have reported a 20% to 30% increased risk of CHD among smokers. Furthermore, angiographic studies confirm that tobacco use is associated with more rapid progression of atherosclerotic lesions and the development of new lesions.[108] For individuals who smoke one pack of cigarettes per day, the RR of MI is sixfold higher for men and threefold higher for women compared with nonsmokers.[109] Meanwhile, the INTERHEART study reported that smoking accounted for 36% of population attributable risk of a first myocardial infarction.[57] In addition, passive cigarette exposure confers a 20% increased risk of CHD and death to nonsmokers, such that it is estimated that 40,000 annual CHD deaths in the United States are caused by secondhand smoke.[110,111] There is a dose-response relationship between passive cigarette exposure and CHD.[112]

Among individuals without CHD, smoking cessation reduces CHD event rate by 7% to 47%.[113,114] The RR of CHD in smokers is reduced within 1 year of quitting. After 5 years of smoking cessation, the CHD risk of former smokers approaches that of nonsmokers.[115] However, the risk for lung, pancreatic, and stomach cancers, as well as for chronic obstructive pulmonary disease, persists for over 10 years. Individuals who continue to smoke in the presence of known CHD have an increased risk of recurrent infarction and death.[116] With the cessation of tobacco use, the risk of recurrent myocardial infarction is reduced by 50%. Post-CABG patients who continue to smoke have a 75% and a 41% increased risk of CHD death and need for revascularization, respectively, compared with those who quit.[117] Similarly, post-angioplasty patients who continue to smoke have a 49% and 44% increased risk of CHD mortality and total mortality, respectively, compared with post-angioplasty patients who quit.[118]

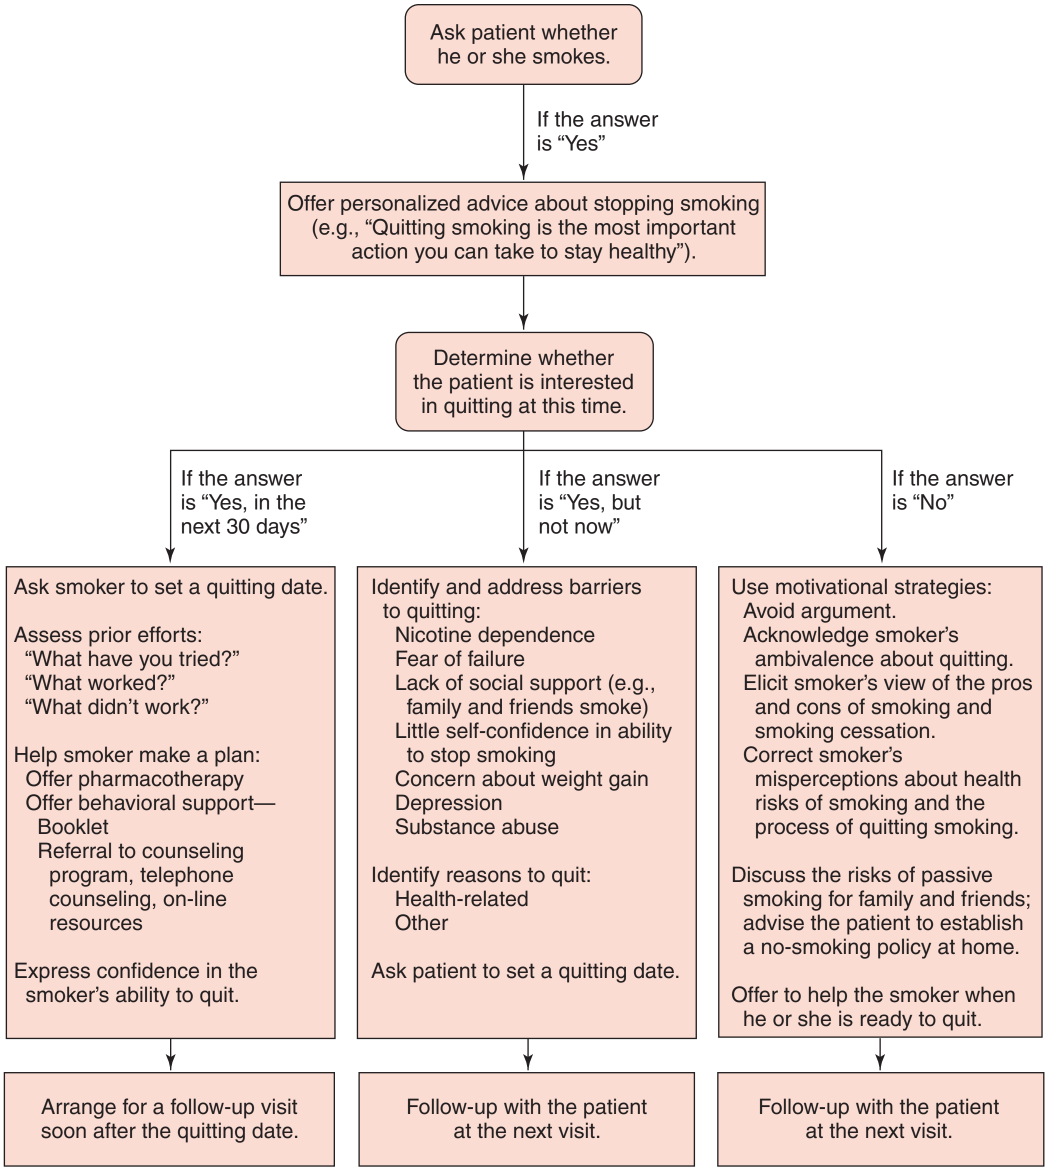

Figure 9–8 Smoking cessation strategy for physicians. This strategy uses the five steps recommended in Public Health Service guidelines: Ask, advise, assess, assist, and arrange follow-up. (From Rigotti N: Clinical practice: Treatment of tobacco use and dependence. N Engl J Med 2002;346[7]:506-12.)

Smoking Cessation Interventions

Reduction in cigarette use requires an improvement in awareness of the adverse cardiovascular outcomes associated with its use among smokers; 60% of two-pack per day smokers were unaware that their cigarette use increases their risk of CHD.[119] Physicians also need to improve communication with patients regarding cessation.[120,121] Figure 9–8 outlines a smoking cessation strategy for physicians. Table 9–7 illustrates drugs used for smoking cessation.

ATHEROGENIC DIET

Poor diet and a sedentary lifestyle are leading causes of preventable death, second only to tobacco use.[122] Diets high in cholesterol and rich in animal fats are linked to the development of CHD, whereas diets rich in vegetables, cereal grains, and fish are associated with prevention of CHD and stroke.[123,124] The Seven Countries Study identified the correlation between high fat/high cholesterol diets and CHD mortality.[124] It had been assumed that the harmful effect of the Western diet is mediated through saturated fat, cholesterol, and the effect of dietary sodium on the lipid profile, BMI, blood pressure, and insulin resistance. However, increasing evidence suggests that diet affects CHD risk beyond its effect on traditional cardiovascular risk factors.[125]

Dietary Fats

Dietary substitution of mono- and polyunsaturated fats for saturated fats improves lipid profiles and reduces CHD risk.[126-128] Trans fatty acids such as those found in stick margarine, vegetable shortening, and deep fat fried foods, increase

Table 9–7 Drugs Used for Smoking Cessation

Product	Daily Dose	Duration of Treatment	Common Side Effects	Advantages	Disadvantages
Nicotine-replacement therapy					
Transdermal patch* 24 hr (e.g., Nicoderm CQ) 16 hr (e.g., Nicotrol)	7-, 14-, 21-mg patch worn for 24 hr† 15-mg patch worn for 16 hr	8 wk 8 wk	Skin irritation, insomnia	Provides steady level of nicotine; easy to use; unobtrusive; available without prescription	User cannot adjust dose if craving occurs; nicotine released more slowly than in other products
Nicotine polacrilex gum (Nicorette)* 2 mg (<25 cigarettes/day) 4 mg (≥25 cigarettes/day	1 piece/hr (<24 pieces/day)	8-12 wk	Mouth irritation, sore jaw, dyspepsia, hiccups	User controls dose; oral substitute for cigarettes; available without prescription	Proper chewing technique needed to avoid side effects and achieve efficacy ‡; user cannot eat or drink while chewing the gum; can damage dental work; difficult for denture wearers to use
Vapor inhaler (Nicotrol Inhaler)*	6-16 cartridges/day (delivered dose, 4 mg/cartridge)	3-6 mo	Mouth and throat irritation, cough	User controls dose; hand-to-mouth substitute for cigarettes	Frequent puffing needed; device visible when used
Nasal spray (Nicotrol NS)*	1-2 doses/hr (1 mg total; 0.5 mg in each nostril) (maximum, 40 mg/day)	3-6 mo	Nasal irritation; sneezing, cough, teary eyes	User controls dose; offers most rapid delivery of nicotine and the highest nicotine levels of all nicotine-replacement products	Most irritating nicotine-replacement product to use§; device visible when used
Non-nicotine therapy					
Sustained-release bupropion (Zyban or Wellbutrin SR)*	150 mg/day for 3 days, then 150 mg twice a day¶	7-12 wk (up to 6 mo to maintain abstinence)	Insomnia, dry mouth, agitation	Easy to use (pill), no exposure to nicotine	Increases risk of seizure (≤0.1%)
Nortriptyline‖	75-100 mg/day**	12 wk	Dry mouth, sedation, dizziness	Easy to use (pill), no exposure to nicotine	Side effects common; should be used cautiously in patients with coronary heart disease
Clonidine‖	0.1-0.3 mg twice a day	3-10 wk	Dry mouth, sedation, dizziness	No exposure to nicotine	Side effects limit use

*This product has been approved by the U.S. Food and Drug Administration as a smoking-cessation aid. The Public Health Service clinical guidelines also recommend it as a first-line drug for smoking cessation.
†The starting dose is 21 mg per day unless the smoker weighs less than 45.5 kg (100 lb) or smokes fewer than 10 cigarettes per day, in which case the starting dose is 14 mg per day. The starting dose should be maintained for 4 weeks, after which the dose should be decreased every week until it is stopped.
‡The user should chew the gum slowly until he or she experiences a distinct taste, indicating that nicotine is being released. The user should then place the gum between the cheek and gum until the taste disappears to allow the nicotine to be absorbed through oral mucosa. The sequence should be repeated for 30 minutes before the gum is discarded. Acidic beverages (such as coffee and soft drinks) reduce the absorption of nicotine and should be avoided for 30 minutes before and during chewing.
§Tolerance develops to local side effects during the first week of use.
¶Treatment should be started 1 week before the quitting date.
‖This agent has not been approved by the U.S. Food and Drug Administration as a smoking-cessation aid. The Public Health Service clinical guidelines recommend it as a second-line drug for smoking cessation.
**Treatment should be started 10 to 28 days before the quitting date at a dose of 25 mg per day, and the dose should be increased as tolerated.
From Rigotti N: Clinical practice. Treatment of tobacco use and dependence. NEJM 2002;346:506-12.

LDL, total cholesterol, triglyceride, and Lp(a) levels, decreases insulin sensitivity, contributes to endothelial dysfunction, and increases platelet aggregation.[129] Dietary substitution of *cis* fatty acids for trans fatty acids reduces LDL and raises HDL.[130] Monounsaturated fatty acids, such as those found in olive oil, canola oil, and dairy products, decrease LDL oxidation and increase insulin sensitivity.[131] Similarly, polyunsaturated fats, such as those in safflower oil, sunflower oil, corn oil, and omega-3 fatty acids decrease total cholesterol, LDL cholesterol, inflammation and platelet aggregation, and they improve insulin sensitivity when substituted for saturated fats.[132] All three classes of fatty acids (saturated, monounsaturated, polyunsaturated fatty acids) increase HDL levels.

Primary prevention trials have shown that diets low in saturated fat and cholesterol reduce CHD risk. Early clinical trials demonstrated that long-term inpatients maintained on diets low in saturated fats and cholesterol had a 35% to 50% reduction in CHD endpoints.[133,134] Secondary prevention trials of dietary fats indicate that dietary intervention can reduce reinfarction rate and that the magnitude of benefit from dietary intervention trials is equivalent to that of lipid-lowering trials.[125,135] Notably, secondary prevention trials that studied diets low in total fat failed to show significant benefit in CHD outcomes. Thus, it appears that the type of fat, rather than total fat, is strongly associated with the prevention of recurrent CHD events. Observational angiographic studies also support the use of low fat diets.[136-139]

Omega-3 Fatty Acids

Evidence from multiple studies shows a positive relation between intake of omega-3 fatty acids and CVD risk reduction.[140,141] Fish and fish oil consumption lowers total cholesterol and LDL cholesterol, increases LDL particle size, improves endothelial function, and decreases inflammation and platelet aggregation.[142,143] A review of eleven studies of omega-3 fatty acids demonstrated an inverse relationship between omega-3 fatty acid intake and fatal CHD, a benefit that was most apparent among those at higher CHD risk.[140] Studies of secondary prevention of CHD with omega-3 fatty acids also demonstrate a protective effect of omega-3 fatty acids.[125,141,144] Omega-3 fatty acids have also been shown to prevent cardiac arrhythmias and to lower the risk of sudden death.[145]

Carbohydrates

Traditional dietary recommendations suggest high intake of complex carbohydrates and avoidance of simple sugars. Simple sugars have a high glycemic index, are more rapidly digested, and produce greater glycemic and insulinemic responses. A 10-year observational study of 75,521 women described a positive association between glycemic load and CHD that was strongest among obese women.[146]

Dietary trends have emphasized reduction in carbohydrate intake rather than dietary fat content. The Atkins diet (high protein, high fat, low carbohydrate diet) when compared with the AHA/NCEP low fat diet showed equivalent weight loss at 1 year, a decrease in triglyceride levels, and an increase in HDL cholesterol without a change in LDL cholesterol or total cholesterol levels.[147] In a review of 107 trials of low carbohydrate diets (Atkins, South Beach, Zone, Sugar Busters) weight loss was related to duration of diet adherence and not to carbohydrate intake. There was no significant adverse effect on blood pressure, lipid, glucose, or insulin levels; and CHD outcomes were not evaluated.[148]

Balanced Diet and Lifestyle Interventions

A balanced dietary approach rather than focused intervention on dietary cholesterol and fat has been studied in the secondary prevention of CHD. The combination of diet and lifestyle change results in a more powerful reduction in CHD endpoints than either intervention alone. A diet rich in fiber, omega-3 fatty acids and folate, low in trans fatty acids and glycemic load, and with a high ratio of polyunsaturated fats to saturated fats, coupled with moderate lifestyle changes including smoking cessation, low-moderate alcohol use, and daily exercise reduced CHD risk by 82% among women participating in the Nurses Health Study.[149] Similar outcomes on CHD risk resulting from diet plus lifestyle interventions were demonstrated in the Oslo Heart Study and the Lifestyle Heart study.[114] However, most primary prevention trials are limited by poor compliance and are inadequately powered to show CHD reduction.[150,151] **Therefore, current recommendations promote a well-balanced diet that is low in saturated fat, cholesterol, and sodium, rich in fruits and vegetables, and has less than 30% of its calories derived from fat. For patients with known CHD or dyslipidemia, less than 7% of calories should be from saturated fats and dietary cholesterol intake should be less than 200 mg per day. A diet rich in monounsaturated fats and omega-3 fatty acids is preferred.**

PHYSICAL ACTIVITY

Studies overwhelmingly demonstrate that in both high-risk patients and healthy individuals, exercise lowers CHD risk. In the Women's Health Initiative cohort, women who exercised vigorously or walked briskly for at least 2.5 hours per week had a 30% risk reduction in cardiovascular events.[152]

These findings were corroborated by the Nurses Health Study, the Harvard Alumni cohort study in men, and the Honolulu Heart Study in the elderly.[153,154] Moreover, large-scale studies indicate that vigorous exercise is not a requirement to observe CHD risk reduction. Cardiac rehabilitation and exercise are also effective in the secondary prevention of CHD.[155] Pooled data of 4000 post myocardial infarction patients show that cardiac rehabilitation reduces cardiovascular events and total mortality by 20% to 25%.[156,157] Additionally, angiographic data have demonstrated that exercise slows the progression of CAD.[158] Finally, an AHA consensus statement on exercise and physical activity recommends 30 minutes of moderate-intensity exercise on most, if not all days of the week, as do the CDC and the American College of Sports Medicine.[159,160]

OBESITY

Overweight is defined as a body mass index (BMI) of 25.0 to 29.9 and obesity as a BMI greater than or equal to 30.0 kg/m^2. Given the escalating worldwide prevalence of obesity, both the U.S. Surgeon General and the WHO have identified obesity as a major health problem.[161] Epidemiological studies

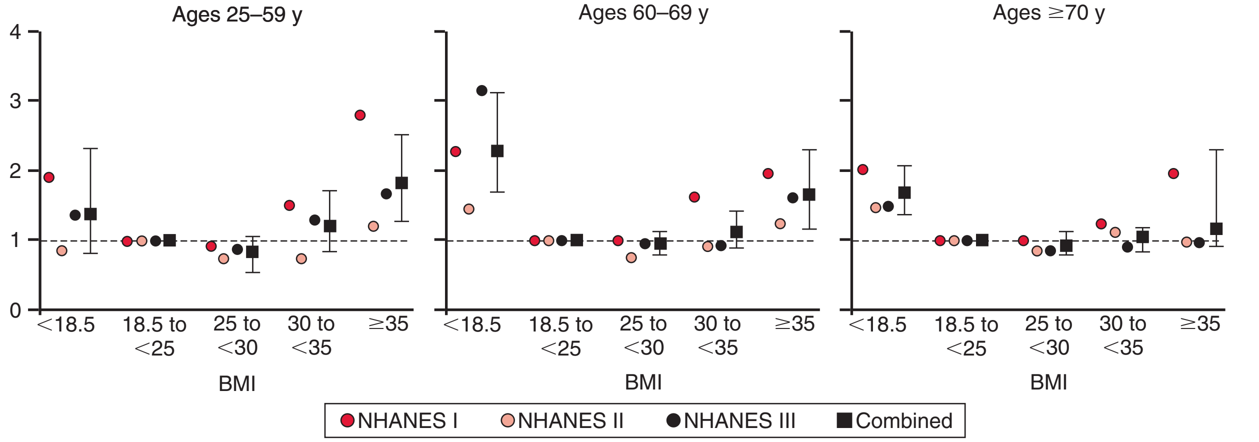

Figure 9–9 Relative risks of mortality by BMI category, survey, and age. U-shaped curve of mortality in which mortality increases with underweight, obesity, and morbid obesity. BMI, body mass index, measured as weight in kilograms divided by the square of height in meters. The reference category with relative risk 1.0 is BMI 18 to <25. Error bars indicate 95% confidence intervals. (From Flegal KM, Graubard BI, Williamson DF, Gail MH: Excess deaths associated with underweight, overweight and obesity. JAMA 2005;293:1861-67.)

demonstrate a positive association between overweight/obesity and all-cause mortality (Fig. 9–9).

The adverse consequences of obesity are mediated through other cardiac risk factors such as hypertension, left ventricular hypertrophy, insulin resistance, diabetes, dyslipidemia, inflammation, and the hypercoagulable state.[120] Although the American Heart Association identifies obesity as a cardiac risk factor, it is unclear whether obesity is itself an independent cardiac risk factor in multivariate analyses that account for hypertension, diabetes, and dyslipidemia.[120] Since the 1960s, there has been a greater decline in the prevalence of CHD risk factors such as dyslipidemia, hypertension, and tobacco use among overweight and obese populations compared with the lean population.[153] Since the U.S. trend for diabetes follows the increasing trend of obesity, the aforementioned net result of a decrease in CHD risk factors may be ameliorated.[162] Abdominal obesity measured by waist circumference confers greater cardiovascular risk than other forms of fat distribution.[62] The metabolic effects of abdominal fat likely contribute to the observation that obesity is a stronger predictor of CHD risk than physical inactivity, despite a common association between obesity and physical inactivity.[163]

Although weight loss improves dyslipidemia, insulin sensitivity, hemoglobin A1c, inflammatory biomarkers, and hypertension, it is unknown whether weight loss reduces cardiovascular events.[62,164,165] Weight loss is best accomplished through a combination of dietary changes and increased physical activity. Figure 9–10 outlines assessment and treatment algorithms for overweight persons.

METABOLIC SYNDROME

The metabolic syndrome is a disorder of insulin resistance exacerbated by obesity, sedentary lifestyle, and genetic predisposition. The Adult Treatment Panel III (ATP III) defined the metabolic syndrome as the presence of three or more of the following:

Waist circumference greater than 40 inches (102 cm) in men and 36 inches (88 cm) in women, serum HDL cholesterol level <40 mg/dL (1.04 mmol/L) in men and 50 mg/dL (1.29 mmol/L) in women, serum triglyceride level of 150 mg/dL (1.69 mmol/L) or more, BP of 130/85 mm Hg or more, serum glucose level of 110 mg/dL (6.1 mmol/L) or more.[24] Using the ATP III guidelines for the metabolic syndrome, 25% or 47 million of U.S. adults have the metabolic syndrome.[166] Although the metabolic syndrome also includes hemostatic dysregulation and inflammation, the ATP III definition does not include elevated fasting insulin, C-reactive protein, fibrinogen, PAI-1, or small dense LDL.[167] The WHO defines metabolic syndrome as the presence of diabetes, impaired glucose intolerance, impaired fasting glucose or insulin resistance plus two of the following:

Blood pressure ≥160/90, serum triglycerides ≥150 mg/dL (1.695 mmol/L), and/or serum HDL cholesterol less than 35 mg/dL (0.9 mmol/L) in men or less than 39 mg/dL (1.0 mmol/L) in women, central obesity with a waist-to-hip ratio <0.90 in men or <0.85 in women, or BMI less than 30 kg/m^2, microalbuminuria with a urinary albumin excretion rate more than or equal to 20 mcg/min or an albumin-creatinine ratio greater than or equal to 20 mg/g.[168]

Although the definition of metabolic syndrome includes established risk factors for CHD, the metabolic syndrome is considered an independent cardiac risk factor for both CHD and diabetes beyond the risk(s) attributed by obesity, hypertension, and dyslipidemia.[120,169] The metabolic syndrome confers a two- to fourfold increased risk of CHD and diabetes.[170,171] In NHANES, the presence of the metabolic syndrome in the absence of diabetes mellitus is associated with a hazard ratio of 2.02 (95% CI 1.42 to 2.89) for CHD mortality and HR 1.40 (CI 95% 1.19 to 1.66) for all-cause mortality (Fig. 9–11).[172]

Intensive lifestyle modification involving weight reduction and exercise is the cornerstone of prevention of CHD in persons with the metabolic syndrome. Given that diabetic vascular complications can be reduced by 50% with intensive treatment of dyslipidemia, hypertension, and blood glucose, and that there is an increased risk of CHD death among individuals with the metabolic syndrome, justification exists for intensive treatment of cardiac risk factors in those persons

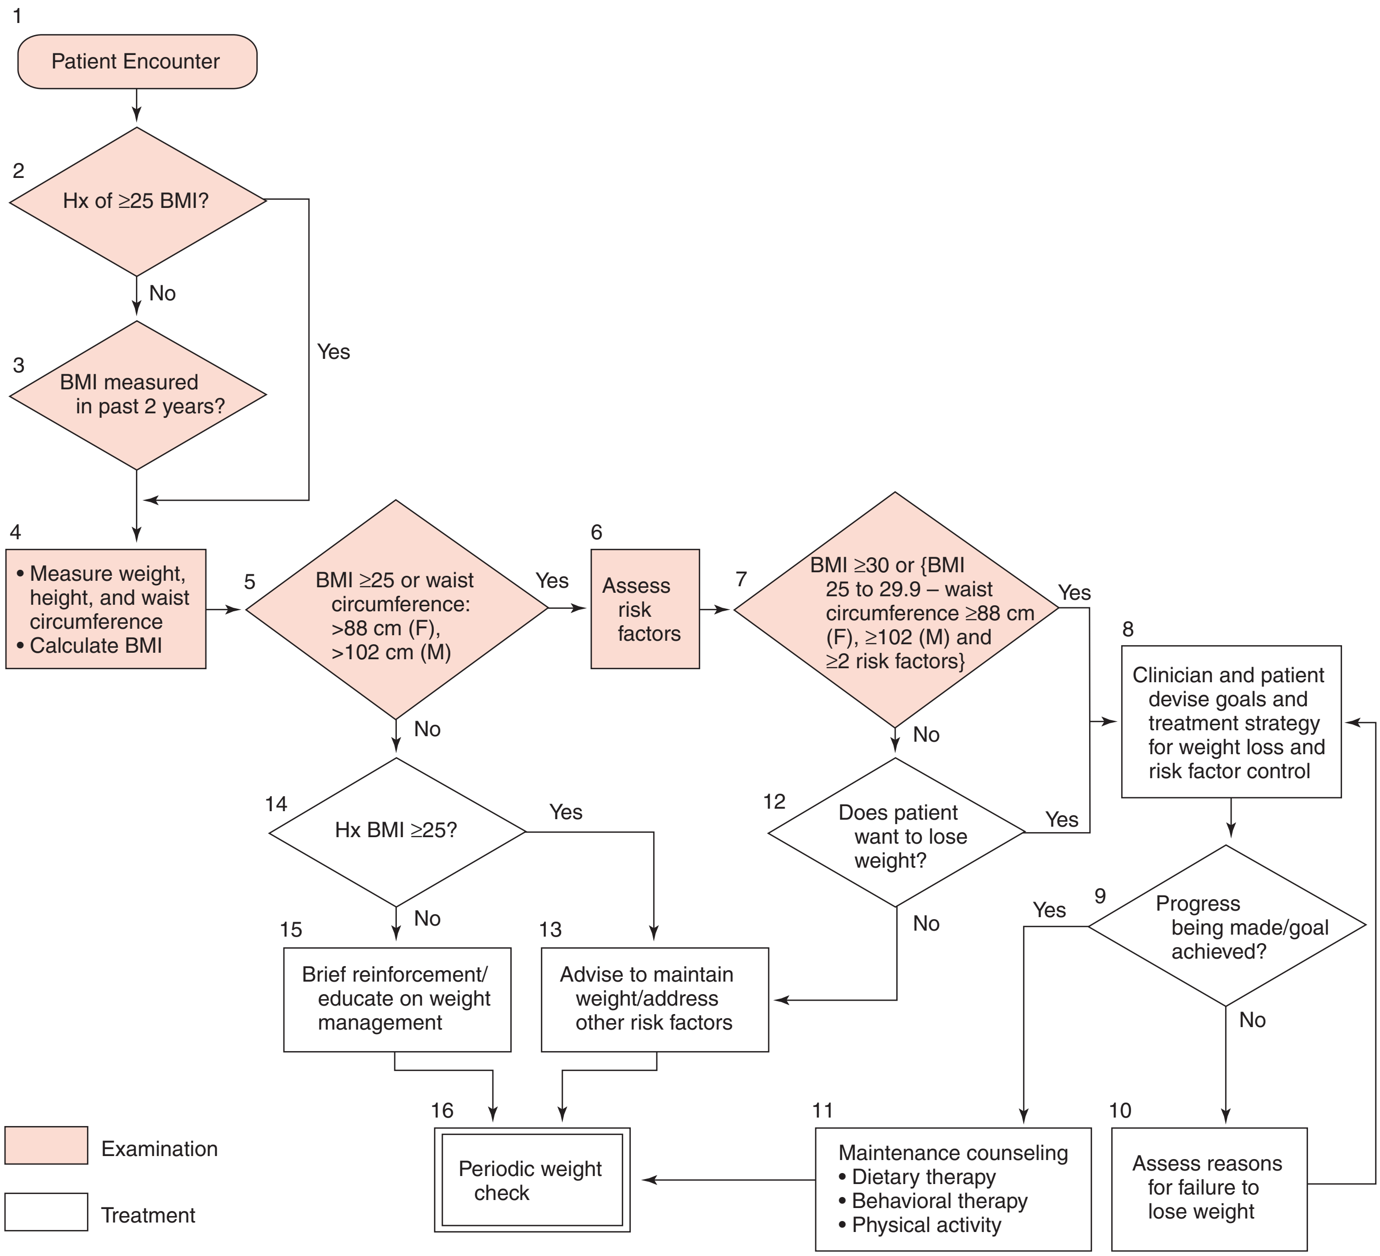

Figure 9–10 Assessment and treatment algorithm for overweight patients. BMI, body mass index; Hx, history. (From Clinical Guidelines on the Identification, Evaluation, and Treatment of Overweight and Obesity in Adults. Bethesda, Md, National Heart, Lung, and Blood Institute, 1998.)

with this diagnosis.[173] For high-risk individuals, pharmacologic therapy may be directed at metabolic risk factors—for example, metformin and thiazolidinediones improve insulin resistance and thus may play a role in preventing CHD. Thiazolidinediones may also exert anti-inflammatory effects in addition to their glucose-lowering effect.[174,175] Ongoing trials are evaluating the efficacy of thiazolidinediones for CHD in patients with impaired glucose tolerance as well as overt diabetes. ACE inhibitors may also be beneficial in the metabolic syndrome for both blood pressure reduction and amelioration of insulin resistance.[176] In the metabolic syndrome, NCEP guidelines should be used for recommendations on the management of dyslipidemias. Low-dose aspirin should be considered on an individual basis in metabolic syndrome patients for the primary prevention of CHD.

DIABETES

Diabetes mellitus is extremely common in the United States and the prevalence is expected to increase.[177] The prevalence of diabetes is highest among African and Native Americans and increases with age. Diabetes is associated with a two- to fourfold increased risk of CHD and stroke, independent of other cardiac risk factors.[9,178-180] The American Heart Association and NCEP/ATP III assigns equivalent risk for

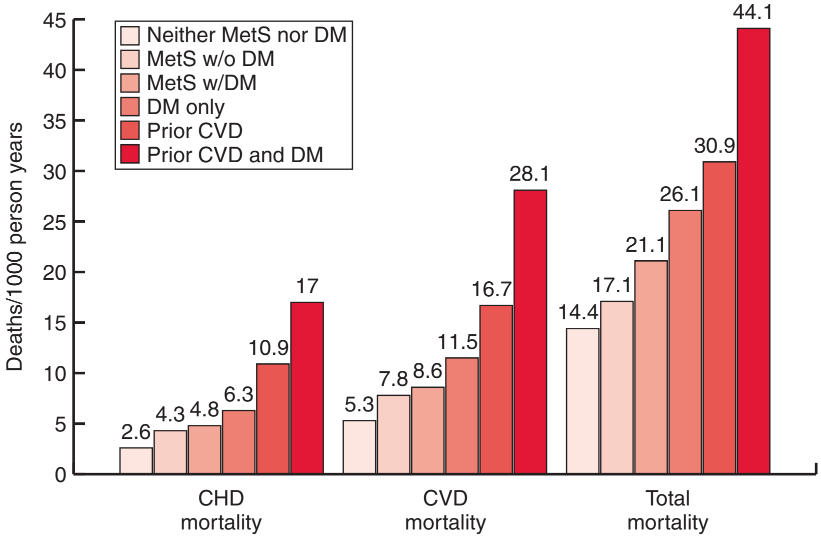

Figure 9–11 Age and gender-adjusted CHD, CVD, and total mortality in U.S. adults with metabolic syndrome (MetS) with and without diabetes mellitus (DM) in the NHANES II study of 6244 adults followed for 13.3 years. (From Malik S, Wong ND, Franklin SS, et al: Impact of the metabolic syndrome on mortality from coronary heart disease, cardiovascular disease, and all causes in United States adults. Circulation 2004;110:1245-50.)

CHD events to diabetics without a history of CHD and nondiabetic patients with CHD.[24,120,181]

The association between glucose intolerance/insulin resistance and cardiovascular risk is not limited to diabetics.[182] There is also a graded rise in cardiovascular risk below the diagnostic threshold for overt diabetes. Diabetes promotes CHD through dyslipidemia, thrombogenicity, endothelial dysfunction, inflammation, and hyperinsulinemia. Twenty-five percent of type II diabetics have dyslipidemia, and 80% of type II diabetics have hypertension.[183,184]

Although strict glycemic control prevents the microvascular complications of diabetes mellitus, the impact of strict glycemic control on macrovascular complications remains unclear.[174,185] The Diabetes Control and Complications Trial (DCCT) of type I diabetics showed that patients randomized to tight glycemic control had less progression of carotid intima-medial thickness over 6 years of follow-up compared with conventional glycemic control and decreased cardiovascular events over 17 years of follow-up.[186,187] However, in the United Kingdom Prospective Diabetes Study where diabetics were randomized to intensive versus conventional glycemic control, there was no significant difference between the two groups in myocardial infarction and stroke with each point of A1c reduction. However, the observation was that the A1c goal in the intensive arm was above that recommended by current guidelines.[188]

Cardiovascular Risk Reduction in Diabetes

The benefit of cardiac risk factor reduction is well documented in diabetes mellitus. Smoking cessation, weight loss, aggressive blood pressure and serum lipid control, as well as the use of low-dose aspirin, confer a mortality benefit in diabetics.[189] Tight blood pressure control might provide greater population cardiovascular risk reduction than intensive glycemic control (Table 9–8); efficacy has been demonstrated for calcium channel blockers, β-blockers, angiotensin-converting enzyme inhibitors, and angiotensin-receptor blockers.[190]

The cardiovascular benefit of lipid-lowering in diabetics has been best studied using HMG-CoA reductase inhibitors. In the Heart Protection Study (HPS), 6000 patients were randomized to simvastatin or placebo; lipid lowering in patients with existing CHD resulted in a 27% risk reduction in major cardiovascular events.[69] The Collaborative Atorvastatin Diabetes Study (CARDS) trial evaluated atorvastatin for primary prevention of CHD in diabetics with normal LDL levels; atorvastatin was associated with a relative risk reduction of 36% to 37% in acute coronary syndrome and major cardiovascular events.[28] Fibrates have also been shown to reduce CHD mortality in secondary prevention.[50]

The cornerstone to CHD prevention in diabetics is lifestyle modification through weight loss. Although there remains a lack of consistent prospective evidence in support of tight glycemic control in the prevention of macrovascular disease, patients should attempt to normalize their A1c to prevent microvascular complications. According to the AHA, NCEP, and the American Diabetes Association, LDL should be aggressively reduced to less than 100 mg/dL for primary prevention of CHD in diabetic patients.[62,120] Similarly, the AHA recommends aggressive control of blood pressure to less than 130/80 mm Hg.[120]

According to the AHA/ACC, exercise treadmill testing in asymptomatic diabetic patients is a class 2b recommendation.[191] The American Diabetes Association/ACC Consensus Statement on Diabetes and Cardiovascular Disease in 1998 recommended noninvasive cardiac testing of asymptomatic diabetics who have peripheral arterial disease, cerebrovascular disease, ECG changes at rest, or two or more cardiac risk factors.[192]

ALCOHOL USE

Alcohol intake (one drink daily for women and two drinks daily for men) is associated with decreased CHD events and stroke in a relationship that is U or J shaped in nature with increasing alcohol consumption.[193-195] A meta-analysis of the risk of stroke and increasing alcohol intake demonstrated that there was a 28% decrease in ischemic stroke among those participants who consumed 12 to 24 g/d of alcohol.[196] However, the mechanism through which alcohol attenuates CHD risk remains uncertain, but is likely related to its effect on HDL-C

and other lipoprotein levels,[197] as well as its effect on inflammation.[198,199] Data suggest that 50% of the protective effect of alcohol is mediated through an increase in HDL-C concentrations.[200] Emerging evidence also indicates that moderate alcohol consumers also have lower levels of CRP, tumor necrosis factor receptors, and interleukin-6.[198,199,201] Alcohol also has a complex relationship with hemostatic parameters; light to moderate alcohol intake is associated with decreased levels of fibrinogen, von Willebrand factor and factor VII, as well as lower levels of fibrinolysis among consumers of >7 drinks weekly.[202] Despite the preceding evidence, public health recommendations for alcohol use and CHD remain cautious owing to the detrimental societal, physiological (e.g., elevated blood pressure, cirrhosis, and cardiomyopathy), and psychological effects related to its consumption.

NOVEL RISK FACTORS OF CARDIOVASCULAR DISEASE

Although the treatment of hyperlipidemia and hypertension has resulted in substantial reductions in mortality from CHD, approximately 40% of persons who develop the disease have one or no traditional risk factors for IHD.[10] A large body of evidence suggests that inflammation plays a prominent role in the development of atherosclerosis.[12,203] Besides basic science data that confirm the role of endothelial dysfunction, oxidation of LDL-C, and hemostatic and thrombotic factors in CAD pathogenesis, angiographic and pathology data also demonstrate that MI occurs more often in coronary arteries that have <70% stenoses and that the aortas of children as young as 15 years of age have atherosclerotic precursor lesions as well.[204] Therefore, data have emerged regarding the role of inflammatory, thrombotic, and hemostatic markers such as high sensitivity C-reactive protein (CRP), fibrinogen, soluble intercellular adhesion molecule, interleukins, Lp(a) and homocysteine, and risk of CVD. Table 9–9 shows established and emerging biomarkers of CVD risk.[205] It is important to understand that for a biomarker to be of use in a clinical setting, it should fulfill several criteria including (1) evidence from multiple prospective studies that clearly establishes a relation between the biomarker and future risk of cardiovascular events; (2) the biomarker should provide independent risk information beyond that available from traditional CVD risk factors or risk scores such as the Framingham Cardiovascular risk score; and (3) standardized assays that are easy to use and are cost effective should be available.

Table 9–9 Clinical Epidemiology of Proposed Novel Biomarkers in the Prediction of Future Cardiovascular Events

C-Reactive Protein

CRP has been the most extensively studied of the novel markers of CVD. Multiple prospective studies indicate that elevated CRP levels independently predict risk of MI, stroke, acute coronary syndrome and sudden death, and risk of recurrent CVD events.[206-208] Interestingly, CRP is specific for predicting CVD mortality and does not predict noncardiovascular mortality.[209] CRP is an acute-phase reactant that consists of five 23-kDa subunits and is produced by the liver in response to inflammatory stimuli and proinflammatory cytokines such as interleukin-6 (IL-6); CRP is also produced by coronary artery smooth muscle cells and affects adhesion molecule expression and activates complement.[210,211]

In studies of risk assessment, CRP has been demonstrated to add prognostic information at all levels of risk of the Framingham Cardiovascular Risk Score (Fig. 9–12).[212] Although CRP levels correlate with the total Framingham Cardiovascular Risk Score, they only minimally correlate with individual components of the score—suggesting that CRP might be capturing other aspects of CVD risk beyond those represented by the traditional CVD risk factors.[213] Additionally, other data show that CRP adds predictive information at all levels of LDL-C such that persons with elevated levels of CRP but low LDL-C levels have a higher absolute risk of cardiovascular events than those with high LDL-C and low CRP levels (Fig. 9–13).[212] CRP has been shown to add prognostic information at all levels of the metabolic syndrome.[214]

Although CRP levels can be lowered by behavioral and pharmacologic interventions, there are no prospective data that demonstrate that lowering CRP levels in apparently healthy persons will attenuate CVD risk. Physical activity, weight loss, smoking cessation, and lipid-lowering medications including statins lower CRP levels. For example, in a study of men participating in the Physicians Health Study, although aspirin treatment prevented the development of MI, the latter was related to baseline CRP levels/degree of inflammation. Aspirin reduced the risk of MI by 55.7% ($P = 0.02$) among men in the highest quartile compared with the lowest quartile of CRP where there was a 13.9% risk reduction in MI that did not reach statistical significance.[215] Most of the data on the association between CRP and lipid-lowering agents relates to the use of 3-hydroxy-3-methylglutaryl coenzyme/statin therapy. Data from a subgroup analysis of the Cholesterol and Recurrent Events (CARE) study showed that compared with placebo, pravastatin significantly reduced CRP levels and risk of recurrent MI at 5 years.[216] Other research in a primary prevention cohort from the Pravastatin Inflammation/CRP (PRINCE) study demonstrated a significant reduction in CRP levels after 6 months.[217] Importantly, the change in CRP levels noted with statin therapy is independent of change in LDL-C levels. Data from the Air Force/Texas Coronary Atherosclerosis Prevention Study (AFCAPS-TexCAPS) among persons without a history of CVD demonstrated that lovastatin prevented coronary events in individuals with hyperlipidemia at all levels of CRP as well as in those with high CRP levels but total cholesterol to HDL-C ratios that were below median values (number needed to treat for 5 years to prevent 1 event = 47, $P = 0.005$ versus 43, $P = 0.02$).[59] The effect of statin therapy on CRP levels represents a class effect.

The AHA/CDC have issued clinical recommendations regarding the use of CRP for global risk assessment. They note that CRP levels <1 mg/L should be considered low risk, 1 to

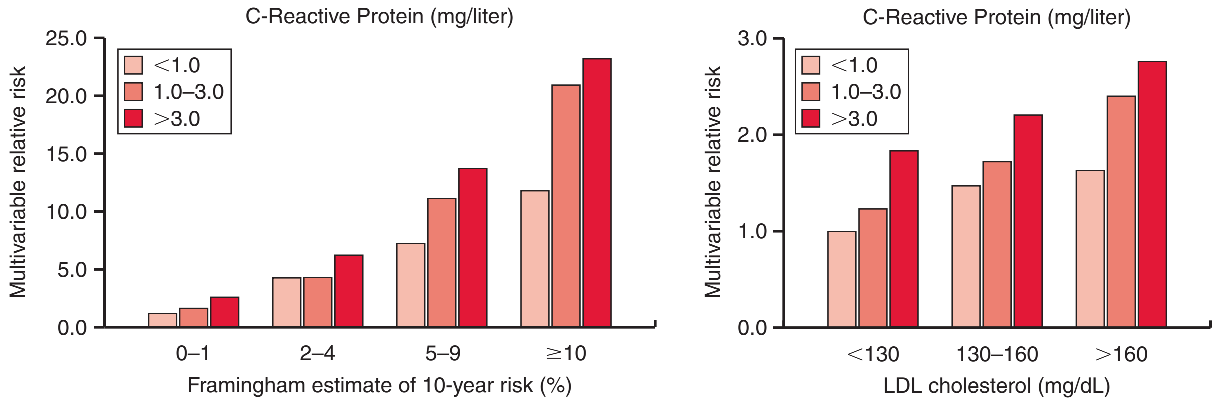

Figure 9–12 Multivariable adjusted relative risk of CVD according to all levels of LDL-C and the Framingham Cardiovascular risk score. To convert values for LDL-C to millimoles per liter (mmol/L), multiply by 0.02586. N Engl J Med 2002;347:1557-65.)

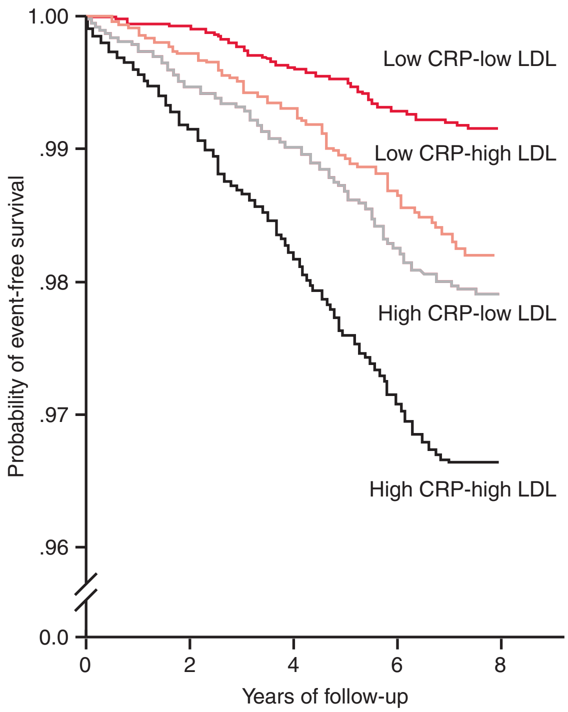

Figure 9–13 Event-free survival in apparently healthy women according to plasma levels of C-reactive protein and low density lipoprotein levels. (Ridker PM, Rifai N, Rose L, et al: Comparison of C-reactive protein and low-density lipoprotein cholesterol levels in the prediction of first cardiovascular events. N Engl J Med 2002;347:1557-65.)

3 mg/L as intermediate risk, and >3 mg/L as high risk for vascular disease. In addition to lipid screening, CRP screening should be performed at the discretion of the physician, particularly in those individuals who are at intermediate risk of vascular disease. It should be noted that CRP levels are affected by concurrent inflammatory illness, obesity, and hormone replacement therapy—all of which raise levels. Much of the data regarding CRP are limited to white populations, but emerging data that suggest that CRP levels might vary by race/ethnic group.[218,219] Primary prevention trials such as the Justification for the Use of statins in Primary Prevention: An Intervention Trial Evaluating Rousuvastatin (JUPITER) are in progress to evaluate whether lowering CRP levels among individuals without a history of CVD will result in a reduction of CVD events.[220]

Homocysteine

A meta-analysis of 30 trials of homocysteine, that included retrospective and prospective trials showed a 25% lower homocysteine level was associated with an OR 0.89 (95% CI 0.83 to 0.86) and 0.81 (95% CI 0.69 to 0.95) of CHD and stroke, respectively.[221] The association between homocysteine levels and CHD risk was independent, continuous, graded, and without a lower threshold beyond which the benefit is lost.

Low dietary intake of folic acid, vitamin B_6, and vitamin B_{12} are associated with hyperhomocysteinemia and increased risk of atherosclerosis.[222] A protective role of high dietary folic acid has been demonstrated among CHD-free men; a 55% reduction in the relative risk of CHD among Finnish men with high folic acid intake has been demonstrated.[223] Folic acid supplementation with 400 mcg daily lowers homocysteine levels by 30% to 42%.[224] It is unclear whether vitamin B_6 and B_{12} supplementation offer additional homocysteine lowering in the absence of nutritional deficiencies.[120]

Replacement of the noted vitamins can correct plasma levels of homocysteine and theoretically reduce the risk of future vascular events. Conflicting evidence exists regarding the use of folic acid supplementation in persons with established CHD. An open-label randomized trial of folic acid supplementation in stable CHD revealed no benefit at 2 years, whereas a randomized trial of supplementation with folic acid, vitamin B_6, and vitamin B_{12} in post-PTCA patients showed a decrease in adverse CHD events at 11 months in the treatment arm.[225,226] By contrast, a randomized trial of folic acid supplementation versus placebo after stent placement showed an increase in in-stent restenosis in the treatment arm.[227]

Although a large body of evidence shows that elevated homocysteine levels are associated with increased CHD risk, screening

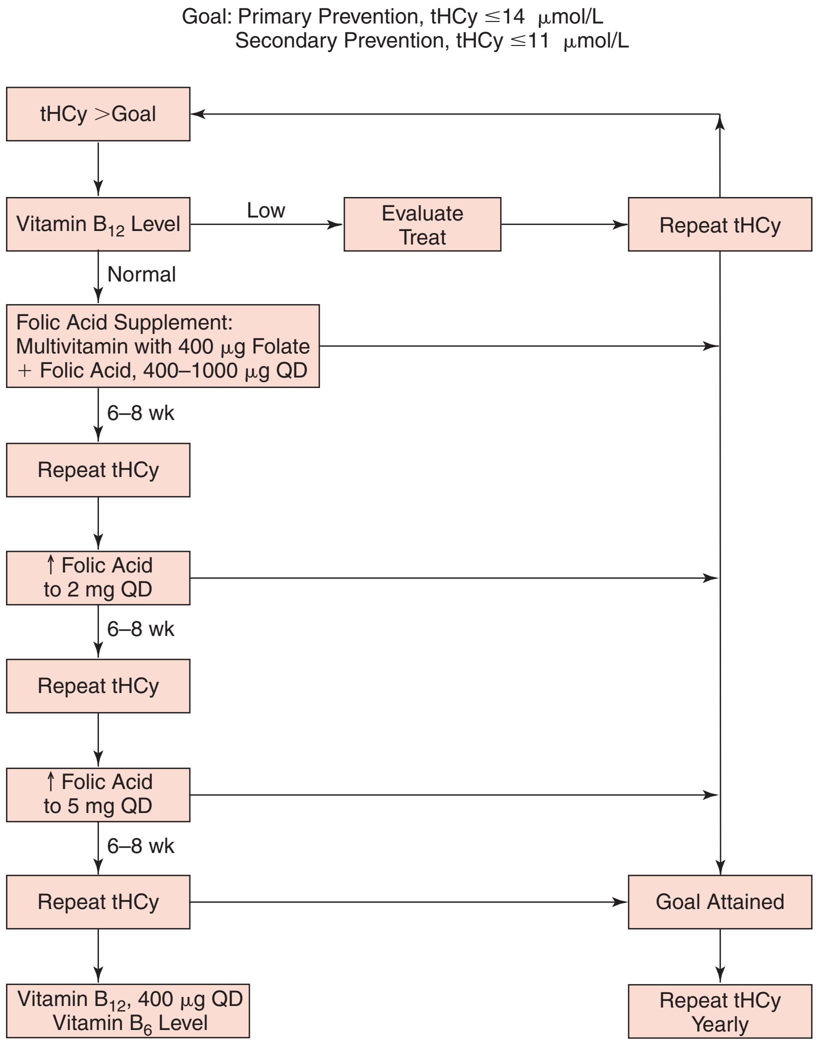

Figure 9–14 Suggested algorithm for treatment of hyperhomocysteinemia. (From Stein JH, McBride PE: Hyperhomocysteinemia and atherosclerotic vascular disease: Pathophysiology, screening, and treatment. Arch Intern Med 2002;158:1201-06.)

of the general population is not yet recommended.[120,228] At the population level in the United States, folic acid has been easily supplemented through the fortification of bread. The AHA recommends screening of persons who have a personal or family history of premature CHD in the absence of traditional risk factors, malnutrition, and malabsorption syndromes, hypothyroidism, chronic renal failure, systemic lupus erythematosus, unexplained venous thrombosis, and patients taking medications that increase homocysteine levels.[229] Screening should be deferred for 2 to 3 months after serious systemic illness. High-risk individuals without a history of CHD should be treated for primary prevention if their homocysteine levels exceed 14 µmol/L. Dietary supplementation with folic acid 1 mg/day is recommended (Fig. 9–14). The addition of vitamin B_6 10 mg/day and vitamin B_{12} 0.4mg/day has not been vigorously proven to be effective. If homocysteine levels fail to normalize in 6 weeks, the dose of folic acid may be increased. For adults with average CHD risk, a daily multivitamin that includes folate is suggested.

Lipoprotein (a)

Lipoprotein (a) has structural homology with plasminogen and is composed of LDL-C that has the apolipoprotein (a) 100 constituent linked by a disulfide bond. Because of its structural similarity to plasminogen, it might compete with the latter to inhibit fibrinolysis. Although its role in promoting CVD is unclear, it induces chemotaxis of monocytes, and affects PAI-1 and tissue factor expression.[51,230] Plasma concentrations of Lp(a) are dependent on APO A isoform size and are genetically influenced.[231]

Multiple studies indicate that elevated levels of Lp(a) predict vascular risk. Blacks tend to have higher Lp(a) levels than other race/ethnic groups but the importance of the latter as a risk factor in this population remains uncertain. Because there is minimal correlation between Lp(a) and traditional CVD risk factors, prospective data demonstrate that the adjustment for the latter results in nominal change in the overall combined risk ratio of 1.6 among persons in the highest tertile of Lp(a) compared with those in the lowest tertile.[232] At present, there are no data that indicate that Lp(a) adds predictive value to the Framingham risk algorithm. It is also unclear whether elevated Lp(a) levels predict CHD risk in all populations. As well, the standardization of commercial Lp(a) assays remains poor owing to varying sensitivity of the assays to APO A size making it difficult to use Lp(a) for widespread screening for CVD.[233] However, measurement of Lp(a) might be useful in persons with premature CHD, renal failure patients, and

among elderly men.[234,235] High-dose niacin reduces Lp(a) levels but the latter therapy has not been proven to reduce the risk of subsequent CHD events.

Hemostatic and Thrombotic Markers

Fibrinolysis and thrombosis are critical components in the pathogenesis of atherosclerosis. Impaired fibrinolysis is, in part, a result of an imbalance between clot dissolving elements such as t-PA and urokinase-type plasminogen activator and PAI-1. PAI-1 is ubiquitous in humans, has a relatively short half-life, and is produced by the vasculature, adipose tissue, and liver and is stored in large quantities in platelets.[236] Its production is regulated by inflammatory cytokines, neurohormonal and metabolic factors including glucose, glucocorticoid and glucosamine responsiveness. Plasma concentrations of PAI-1 are also affected by polymorphisms in the PAI-1 gene; the 4G/4G genotype is associated with the highest levels of PAI-1.[170] Basic science evidence demonstrates that transgenic mice that overexpress human PAI-1 develop coronary occlusions and MI [237] and that PAI-1 is localized in atherosclerotic plaques.[238-240] Several reports show that PAI-1 predicts IHD risk in healthy middle-aged men, young survivors of MI, and other post-MI patients.[241,242] However, there are no consistent prospective data that show that PAI-1 improves CVD risk prediction beyond that of traditional risk factors/algorithms. Moreover, the need for proper specimen collection, the circadian variation of PAI-1 activity (high levels in the morning and lower levels in the afternoon), and the responsiveness of PAI-1 expression to estrogen, insulin, and angiotensin II complicate the ability of PAI-1 usage in the clinical setting. Angiotensin converting enzyme inhibitors result in a decrease of PAI-1 antigen levels in humans.[243,244]

Tissue plasminogen activator is another member of the fibrinolytic system that is secreted by the vascular endothelium in response to bradykinin and substance P, is stored in endothelial cells, has a short half-life and unlike PAI-1 is not influenced by circadian factors.[205] Elevated levels of t-PA are associated with increased vascular risk[13,245]; t-PA is believed to interact with PAI-1 to form stable complexes that have a longer circulatory time than t-PA. The use of t-PA in clinical practice is also hindered by the lack of standardized commercial assays and prospective data that show that measurement of t-PA adds predictive utility to lipid screening or cardiovascular risk scores.

Fibrinogen

Multiple prospective studies have demonstrated a relationship between fibrinogen and future cardiovascular events. A meta-analysis of 22 studies found that the CVD risk estimate associated with the highest tertile of fibrinogen versus the lowest tertile was 1.99 (95% CI 1.85 to 2.13).[246] Elevated baseline levels of fibrinogen are also associated with an increased risk of stroke and peripheral arterial disease.[246,247] Factors that increase fibrinogen include smoking, diabetes, obesity, hormone replacement therapy, and age; levels are reduced by moderate alcohol use, exercise, and certain lipid-lowering agents—fibrates and niacin. Although fibrinogen predicts risk of vascular events, several challenges hinder its usefulness for risk assessment in the prevention of CVD, including the lack of clinical data that show benefit in reducing CVD events by lowering fibrinogen levels,[248] its strong correlation with levels of other inflammatory markers such as CRP (that might suggest that raised levels reflect the general inflammatory state of atherothrombosis) and sometimes wide variations in serum levels.

NONINVASIVE ASSESSMENT OF VASCULAR DISEASE

Appropriate assessment of asymptomatic patients at intermediate risk for vascular disease has been the subject of intense study over the past decade. Although low-risk persons do not need therapy, and high-risk persons usually qualify for defined interventions, intermediate-risk persons compose a group of people who need refined risk assessment. Imaging modalities might help to provide improved risk assessment among intermediate-risk persons.[249]

Ankle-Brachial Index

Screening for lower-extremity peripheral arterial disease (PAD) is performed using the ankle-brachial index (ABI), a ratio of systolic blood pressure in the ankle arteries to the systolic blood pressure in the brachial arteries. ABI is an inexpensive screening tool used for diagnosing peripheral arterial disease and increasing awareness of PAD in the primary care setting. Prevalence of peripheral arterial disease in primary care practices is high, and PAD is unlikely to be diagnosed. Because of the latter, PAD patients are less likely to be referred to smoking cessation programs or treated for their CVD risk factors.[250] In persons without peripheral arterial disease, systolic pressures are higher in the periphery than in vessels closer to the heart owing to arterial taper.[251]

Normal ABI values are generally >1.00 and ABI values <0.90 are sensitive and specific for the presence of peripheral artery disease.[252,253] Although there is good evidence that values <0.90 are abnormal, less is known about the meaning of borderline values. ABI categories include an ABI of 0.90 to 0.99 that represents borderline ABI; 1.10 to 1.29 is considered a normal ABI; and >1.30 a high ABI. The importance of this classification on clinical outcome is unclear.[254] A few studies have suggested that values >1.50 may represent calcification of peripheral arteries[255] but further study of such thresholds is needed.

Approximately 25% to 30% of elderly individuals have a low ABI. For example, among the elderly, a low ABI value carries a relative risk of 6.3 for a CVD mortality and 3.1 for all-cause mortality compared with normal ABI values.[256] The utility of ABI measurements has also been studied in different ethnic groups. The Multi-Ethnic Study of Atherosclerosis (MESA) found that ABI was significantly associated with the degree of subclinical atherosclerosis in the coronary and carotid arterial beds across ethnicities.[254]

Electron-Beam Computed Tomography

Because previous studies have indicated a relationship between coronary artery calcium and mural atheromatous plaque,[257-259] electron-beam, ultrafast CT (EBCT) was proposed as a way to measure and quantify coronary artery calcium levels.[260] Indeed, some studies have found a correlation

between the total mass of coronary artery calcium as reflected by the calcium score, and the total mass of atherosclerotic plaques as well as the number of arteries and segments with greater than 75% reduction in luminal diameter.[261-264] Coronary artery calcification and calcium score increases with age, and the usefulness of EBCT for identifying patients at higher risk for significant coronary artery disease decreases with increasing age.[260]

Some studies indicate that coronary calcium measurement can add incremental CHD risk prediction information for intermediate- to high-risk patients as well influence patient behavior.[265,266] For example, in one postmortem study, more than 97% of arterial segments without calcification were free of hemodynamically significant stenosis and hemodynamically significant stenosis was not present in vessels without calcification.[261] Also, some data show that self-referred subjects who have high coronary calcium scores were more likely to adhere to HMG-CoA reductase therapy than their counterparts with low scores.[267]

Potential limitations regarding the widespread use of EBCT include that its specificity is only 75% and that the total volume of calcification by EBCT may correlate more closely with the total burden of atherosclerotic plaque than with lumen stenosis.[267,268] Also, there may be limitations in the ability of the coronary calcium score to predict CHD risk in all ethnic groups. Additionally, the calcium screening method does not address the degree of plaque stability or give any physiologic information.

The AHA consensus statement on the use of electron-beam computed tomography for CHD screening [269] notes that, despite its high sensitivity, the low sensitivity of EBCT precluded, in part, recommendation for use to diagnose coronary artery disease.[270] Although EBCT might add information to traditional risk factors, EBCT cannot yet be used in lieu of coronary angiography.

Common Carotid Intima-Media Thickness (IMT)

Another measure of peripheral arterial disease is carotid intima-media thickness (IMT) by B-mode ultrasound.[271] IMT gives information on atherosclerotic wall changes that cannot be obtained by conventional contrast angiography or MRI.[272] Carotid arteries have been particularly favored for study as a peripheral artery because they are relatively superficial, large in caliber, and are relatively immobile, thereby allowing easy imaging.

The carotid IMT measure is associated with age, elevated levels of major cardiovascular risk factors such as dyslipidemia, hypertension, and cardiovascular disease.[273-277] Carotid IMT also correlates with the angiographic presence and extent of coronary artery disease.[278,279] For example, in populations without known coronary artery disease, high carotid IMT score is associated with an elevated risk for further cardiovascular events.[273,280] In one study, asymptomatic people older than the age of 50 years with abnormal intimal medial thickness (IMT) had a fivefold increased risk than that ascribed by traditional coronary risk factors for the occurrence of future cardiovascular events.[273,281,282] Another study demonstrated that carotid arterial intima-media thickness predicted coronary events in men 40 to 59 years of age who had previously had coronary artery bypass graft surgery.[281] Also, some evidence indicates that there may be incremental predictive value of carotid ultrasonography in assessing coronary risk in diabetic patients.[283]

Carotid IMT is affected by lifestyle factors such as cigarette smoking, cholesterol intake, and body mass index. Treatment of these factors results in improvement of IMT measurements; for instance, lipid lowering reduces cardiovascular events and mortality and decreases the degree of IMT.[284-286] Before routine measurement of IMT in clinical practice, methods of measurement must be standardized and precise thresholds must be set that accurately indicate levels of CHD risk.[287]

Exercise Testing

Exercise electrocardiography has been proposed as a screening tool for asymptomatic subjects thought to be at intermediate risk for developing clinical coronary disease. Important measures during exercise testing that predict CHD risk include nonelectrocardiographic measures such as exercise or functional capacity, chronotropic response, heart rate recovery, and the development of ventricular ectopy.[120] Many studies have shown that the most important marker of vascular risk yielded by exercise testing is the measure of functional capacity. Population-based studies have confirmed the importance of functional ability to predict CHD mortality and cardiovascular risk in asymptomatic patients.[288-290] The role of exercise testing in asymptomatic patients for primary prevention has not yet been clearly defined.[120] It is unknown whether routine exercise testing in selected asymptomatic patients attenuates cardiac morbidity and mortality.[291]

Psychosocial Factors

Some studies indicate a link between depression, anger, hostility, and IHD.[292,293] Most studies show an increase in risk of CHD events with higher depression scores. The data linking anxiety, anger, and hostility to IHD are not as consistent as the data related to depression and are limited among other issues by the lack of women in available research reports and nonstandardized screening instruments.[292,294] However, data from the Nurses Health Study showed that phobic anxiety as measured by the Crown Crisp index was associated with an increased risk of sudden cardiac death.[295] The mechanism linking psychological symptoms and IHD are complex and not well elucidated but include adverse lifestyle behaviors such as physical inactivity, noncompliance with care, smoking, hypercortisolemia, hemostatic perturbations, impaired vagal tone, and reduced heart rate variability.[292]

Low socioeconomic status is another factor associated with increased risk of CVD. Although socioeconomic status encompasses multiple factors including education, income, neighborhood environment, social status and support, the relationship between socioeconomic level and CVD is likely, in part, a result of chronic physical and psychological stress. Pathophysiologically, hypothalamic-pituitary axis dysfunction, lipid and hemostatic abnormalities all contribute to the physiological effects of chronic stress on the vascular system.[296,297] Interventions aimed at reducing morbidity and mortality related to psychological complaints should be multidisciplinary in nature and must encompass adequate screening and referral and management of affected patients. Table 9–10[294] outlines potential behavioral and medical interventions.

Table 9–10 Behavioral and Medical Interventions for Psychosocial Risk Factors

		Intensity of Intervention	
Type of Intervention	Targeted Condition	Less Intense*	More Intense
Exercise training	Psychologic distress	Exercise prescription plus general guideline	Supervised exercise
Nutritional counseling	Management of stress by overeating	Provide nutritional advice	Supervised dietary instruction, weight management, and behavior modification
Relaxation training	General stress and stress caused by specific situations	Advise patient to initiate relaxation training; provide audiotapes, videotapes, or instructional scripts	Teach muscle relaxation, imagery, autogenic training, diaphragmatic breathing, or biofeedback
Stress management	General stress and stress caused by specific situations	Recommend vacations, hobbies, yoga, relaxing music, pets, or pleasurable activities	Teach behavioral strategies (e.g., problem-solving, self-monitoring, appropriate goal-setting, relapse-prevention techniques)
Social support	Poor structural or functional support	Provide specific social suggestions (e.g., join walking groups or engage in socially altruistic activities)	Use staff as a support base, enroll patient in support group, or facilitate family involvement
Health information	Specific stress situations (e.g., at work or home) or low health literacy	Provide situation-specific information in the forms of books, articles, pamphlets, audiotapes, videotapes, or Web sites	Discuss and answer patient questions regarding materials related to health and treatment recommendations.

*Most amenable to direct cardiologist management.

Postmenopausal State

Earlier observational studies such as the Nurses Health Study had suggested that users of estrogen had about one half the risk of CHD as nonusers (relative risk of 0.51, 95% CI of 0.37 to 0.70),[298] and that overall hormone replacement therapy (HRT) lowered CVD risk 40% to 50%. Given the other benefits of estrogen replacement, such as reduction in bone loss, it became common clinical preventive practice in the early 1990s to recommend hormone therapy for postmenopausal women, those women with coronary heart disease, and those at high risk for coronary heart disease.[299] However, a series of studies has emerged that disproves the original observations. Trials that used estrogen and medroxyprogesterone acetate among women with established angiographically verified coronary artery disease[300] and older women with coronary-artery atherosclerosis[301] showed that combination HRT treatment did not affect the progression of coronary atherosclerosis. Subsequently, the publication of the Heart and Estrogen/progestin Replacement Study (I and II) in secondary prevention, and the Women's Health Initiative Study (WHI) in primary prevention, changed the guidelines for hormone replacement therapy.

HRT and CHD Prevention

The HERS trial randomized 2763 women with known coronary artery disease to either estrogen plus medroxyprogesterone acetate or placebo and followed them for the occurrence of nonfatal myocardial infarction or CHD death for an average follow up of 4.1 years.[302] HRT treatment did not reduce the overall rate of CHD events and increased the rate of thromboembolic events (HR 2.89, 95% CI, 1.50 to 5.58). Higher CHD risk was observed during the first year of therapy, and although CHD risk decreased during years 3 to 5, this did not persist at long-term follow-up.[303]

The results of the Women's Health Initiative (WHI) echoed those of the HERS trial in a primary prevention population. Among 16,608 postmenopausal women without history of CHD, aged 50 to 79 years at baseline randomized to estrogen plus medroxyprogesterone acetate or placebo,[304] the overall risks of HRT exceeded the benefits after 5.2 years of follow-up. HRT was associated with a hazard ratio for CHD of 1.24 (95% CI, 1.00 to 1.54) compared with placebo.

Recommendations

In light of these findings, the U.S. Preventive Services Task Force (USPSF) issued recommendations for the prevention of chronic conditions in postmenopausal women in 2005.[305] Although the use of combined estrogen and progestin resulted in both benefits and harms—with benefits that include reduced risk for fracture and colorectal cancer—given recent data, they recommended against the routine use of combined estrogen and progestin or unopposed estrogen for the prevention of chronic conditions in postmenopausal women (Grade D recommendation). Similarly, the 2004 AHA Scientific Statement for Cardiovascular Disease Prevention in Women[306] concluded that combined estrogen plus progestin hormone therapy should not be initiated to prevent CVD in postmenopausal women

(Class III, Level A) and that combined estrogen plus progestin hormone therapy should not be continued to prevent CVD in postmenopausal women (Class III, Level C).

CAD IN DEVELOPING COUNTRIES

While CVD rates have been declining in many developed nations, in developing nations CVD rates continue to increase and account for 80% of worldwide CVD burden. It is estimated that there were 17 million CVD deaths worldwide in 2002—representing the main cause of death.[1] In developing nations, the mortality from CAD is estimated to be greater than 4.5 million, a number that is expected to exceed 8 million by 2020. Some clinicians estimate a 120% and 137% increase in CAD death rates among women and men, respectively.[306,307] Prevalence rates for CAD will be fueled by explosions in the number of persons affected by diabetes, obesity, and the continued increase in tobacco use—particularly among the youth. Chronic diseases, of which CVD represents the majority of cases, prevails over infectious diseases and has resulted in the so called "double burden of disease" in developing nations where early in life, persons/populations are afflicted with infectious diseases only to later be plagued with chronic illnesses such as CAD due to an increase in life expectancy in many countries.

The continuing increase of CAD cases in developing countries can be attributed to multiple factors including, but not limited to, societal transitions from rural to urban communities, the adoption of Western diets that are high in saturated fats and sugars, and improvements in longevity.[308] Although there is a paucity of data from most developing countries, CAD accounted for at least one third of CVD deaths in India and more than fifty percent of deaths in urban areas of China.[308,309] Among black Africans, CAD prevalence is relatively low compared with urban whites and Asians; however, statistics are hampered by the lack of comprehensive epidemiological studies and disease misclassification. The INTERHEART study, a case control study of modifiable risk factors for MI in 52 countries demonstrated that psychosocial factors, smoking, and APO B/APO A1 ratio were dominant factors in the risk for MI worldwide, and that the traditional risk factors for MI in market economies accounted for approximately 90% of the population attributable risk for MI. In the outpatient setting, the Reduction of Atherothrombosis for Continued Health (REACH) Registry collected data on atherosclerosis risk factors in 44 countries demonstrated that risk factor profiles for CAD are similar across non-African nations across the world.[310] These data suggest that the basic tenets of prevention of CAD in developing nations could be similar to those that govern prevention goals in industrialized nations.[57]

The operative aspect of prevention strategies in developing countries remains a challenge. First, the "double burden of disease" places an enormous strain on government and international agency budgets. Additionally, many economies benefit significantly from the production of harmful tobacco products, thereby ensuring that prevention efforts in some nations will conflict with national economies—making it harder to implement beneficial strategies. Public health programs to promote healthy dietary and physical activity strategies are in direct competition with individual and societal wealth transitions that confer more urban living and Western diets. Effective prevention strategies in developing nations should include the collection of risk factor information and determinants of behavior in an organized manner through large-scale epidemiological studies, public programs that promote healthy eating and physical activity, accurate education/communication of current CVD disease burden to key policy makers, provision of inexpensive effective pharmacologic therapies, and the control of tobacco products (Table 9–11).[311]

Table 9–11 Proposed Strategies to Deal with CVD in Developing Countries

1. Development of reliable statistics on mortality, morbidity, and risk factor levels in multiple developing countries (e.g., through sentinel surveillance programs).
2. Use available information on the importance of conventional risk factors (tobacco smoking, high BP, elevated lipids, etc.) to develop strategies for prevention in developing countries.
3. Encouraging national policies on agriculture (to make fruits and vegetables more affordable and promote the consumption of whole grains), urban planning (to promote physical activity during daily life) and effective tobacco control.
4. Performing large scale epidemiologic studies to document societal and individual factors influencing lifestyles and how these relate to risk factors and CVD.
5. Developing research capacity for investigating the determinants and modifiers of chronic disease such as CVD, obesity, and diabetes. Strengthening and improving the efficiency of existing national funding bodies for research. Raising the priority of chronic disease (including CVD), as being worthy of research funding by national and international organizations.
6. Encouraging and documenting the use of simple secondary prevention measures through registries and improving optimal prescribing through physician education programs.
7. Ensuring that proven therapies are affordable to those with CVD or for those with CV risk factors.
8. Raising awareness among the public of the health hazards of smoking, physical inactivity, and diets high in saturated fats and a high glycemic load.

PHARMACOLOGIC INTERVENTIONS FOR PRIMARY PREVENTION

Aspirin

Several pharmacologic interventions have proven to be highly effective in the secondary prevention of cardiovascular disease. The role of aspirin in secondary prevention has been well-established. For example, the Antithrombotic Trialists' Collaboration showed that aspirin reduced the risk of cardiovascular events, myocardial infarction, and ischemic stroke in men and women.[312] Other meta-analyses also demonstrate

Table 9–12 Overview of Primary Prevention Trials of Aspirin Therapy

Study (Date and Reference Number)	Patients	Dose (mg)	Follow-Up	Cardiovascular Death: RR (95% CI)	Nonfatal Myocardial Infarction: RR (95% CI)	Nonfatal Stroke: RR (95% CI)
Physicians' Health Study (1988 #315)	22,071 men	325 on alternate days	5 yr	0.96 (0.80-1.14)	0.59 (0.47-0.74)	1.20 (0.91-1.59)
British Doctors' Trial (Peto, 1988 #318)	5139 men	500 mg daily	6 yr	0.93 (0.79-1.07)	0.97 (0.78-1.16)	1.13 (0.89-1.37)
Early Treatment of Diabetic Retinopathy Study (1992 #317)	3711 men and women	650 mg daily	5 yr	0.87 (0.70-1.10)	0.83 (0.66-1.04)	1.17 (0.79-1.28)
Thrombosis Prevention Trial (1998 #316)	5499 men	75 mg daily	6.4 yr	NA	0.68 (0.52-0.88)	NA
Hypertension Optimal Treatment Study (Hansson, 1998 #319)	18,790 men and women	75 mg daily	3.8 yr	0.95 (0.75-1.20)	0.64 (0.49-0.85)	0.98 (0.78-1.24)
Women's Health Study (Ridker, 2005 #321)	39,876 women	100 mg every other day	10 yr	0.95 (0.74-1.22)	1.02 (0.84-1.25)	0.83 (0.69-0.99)
Primary Prevention Trial (de Gaetano, 2001 #320)	4495 men and women	100 mg daily	3.6 yr	0.77 (0.62-0.95)	0.69 (0.38-1.23)	0.67 (0.36-1.27)

reductions in mortality and nonfatal CVD event rates among patients with prior MI, stroke, bypass surgery, angioplasty, peripheral vascular surgery, or angina.[313,314]

In primary prevention, randomized trials indicate that low-dose aspirin decreases the risk of a first myocardial infarction in men, with little effect on the risk of ischemic stroke, but the effects of aspirin appear to be different in women. Large-scale trials have assessed the benefits of low-dose aspirin in the primary prevention of CVD[315-320] and are shown in Table 9–12. In aggregate, among men, a summary of data from the Physicians Health Study, the British Doctors Trial, the Thrombosis Prevention Trial, the HOT study, and the Primary Prevention Project indicate that aspirin therapy is associated with a significant, 32% reduction in the risk of myocardial infarction (RR 0.68, 95% CI, 0.54 to 0.86; $P = 0.001$) and a nonsignificant increase in the risk of stroke (relative risk 1.13; 95% CI, 0.96 to 1.33; $P = 0.15$).[51]

By contrast, data from the Women's Health Study (WHS), of 39,876 initially healthy women 45 years of age or older who were randomized to receive 100 mg of aspirin on alternate days or placebo, demonstrated a nonsignificant reduction in CHD risk with aspirin compared with placebo (relative risk, 0.91; 95% CI, 0.80 to 1.03; $P = 0.13$).[321] There was a 17% reduction in the risk of stroke in the aspirin group compared with the placebo group (relative risk, 0.83; 95% CI, 0.69 to 0.99; $P = 0.04$). The latter was due to the net effect of a 24% reduction in the risk of ischemic stroke (relative risk, 0.76; 95% CI, 0.63 to 0.93; $P = 0.009$) and a nonsignificant increase in the risk of hemorrhagic stroke (relative risk, 1.24; 95% CI, 0.82 to 1.87; $P = 0.31$). Compared with placebo, aspirin had no significant effect on the risk of fatal or nonfatal myocardial infarction (relative risk, 1.02; 95% CI, 0.84 to 1.25; $P = 0.83$) or death from cardiovascular causes (relative risk, 0.95; 95% CI, 0.74 to 1.22; $P = 0.68$). Only in women older than age 65 did aspirin appear to significantly reduce the risk of major cardiovascular events, ischemic stroke, and myocardial infarction. In the same report, a meta-analysis of earlier studies was also performed, combining five large studies of aspirin with

Table 9–13 Guide to Cardiovascular Disease Risk Reduction in Apparently Healthy Patients

Risk Factor	Goal	Recommendations
Smoking	Complete cessation	Ask about smoking during routine evaluations. Encourage patient (and family members) to stop smoking. Provide counseling and information about enrolling in formal stop-smoking programs, offer access to nicotine replacement therapy/pharmacotherapy. Continue to evaluate.
High BP	<140/90 mm Hg	Measure BP in adults at least every 2 yr. Recommend healthy lifestyle practices, including weight control, increased physical activity, smoking cessation, and sodium restriction. If BP is 140/90 mm Hg after 3 mo of lifestyle modification or initial BP is 160/100 mm Hg, add antihypertensive medication to lifestyle modification.
High cholesterol	LDL-C <160 mg/dL if patient has 0-1 other risk factors,* <130 mg/dL if two or more risk factors; also HDL-C >40 mg/dL and TG <200 mg/dL	If LDL-C is elevated, rule out secondary causes such as liver or thyroid dysfunction. Begin Therapeutic Lifestyle Changes (diet: saturated fat <7% of calories, cholesterol <200 mg/day, carbohydrates 55% of calories, protein 15% of calories, polyunsaturated fat up to 10% of calories, monounsaturated fat up to 20% of calories; weight management; and increased physical activity). If target LDL (<130 mg/dL for patients with two risk factors; <160 for patients with 0–1 risk factors) is not met after 6 weeks, consider increased viscous (soluble) fiber (10-25 g/day) and plant stanols/sterols (2 g/day) to enhance LDL lowering. If target LDL still not met after 6 more weeks, consider drug therapy. If HDL-C <40 mg/dL, emphasize weight management and physical activity. Consider niacin or fibrate if patient has two or more risk factors and elevated LDL-C.
Physical inactivity	30 min of moderate physical activity on most, if not all, days of the week.	Ask about routine physical activity and exercise habits. Encourage increased physical activity in daily life as well as a regular exercise program. Recommend medically supervised activities at least initially for patients with comorbidities or low functional capacity.
Weight	BMI <25 kg/m^2, waist circumference <40 inches for men and <35 inches for women; at a minimum, no increase in weight	Routinely measure patient's weight and height, as well as waist and hip circumferences.
Menopause		Combined estrogen plus progestin should not be used to prevent CVD in postmenopausal women
Antioxidants		Antioxidant supplements should not be used to prevent CVD pending trial results
Psychosocial	Evaluate for Depression/Anxiety Disorders. Assess structural/functional support.	Refer to programs/activities that will enhance social support and refer/treat depression/anxiety. Focus on management of overall stress and specific situations. Refer to programs/activities that will enhance social support and refer/treat depression/anxiety. Focus on management of overall stress and specific situations

*Risk factors include age (men ≥45 yr, women ≥55 yr or postmenopausal), smoking, hypertension, diabetes, family history of congestive heart disease in first-degree relative, and HDL-C <40 mg/dL. If HDL-C ≥60 mg/dL, subtract one risk factor.
BMI, body mass index; BP, blood pressure; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol; TG, triglycerides.
Adapted and modified from Grundy SM, Balady GJ, Criqui MH, et al: Guide to primary prevention of cardiovascular diseases. Circulation 1997;95:2329-31.

Table 9–14 Guide to Cardiovascular Disease Risk Reduction for Patients with Coronary and Other Vascular Disease or Diabetes

Risk Intervention	Goal	Recommendations
Smoking cessation	Complete cessation	Strongly encourage patient and family to stop smoking. Provide counseling, nicotine replacement, pharmacotherapy, and formal cessation programs as appropriate.
BP control	<140/90 mm Hg	Initiate lifestyle modification—weight control, physical activity, moderation of alcohol intake, moderation of sodium intake—in all patients with BP >140/90 mm Hg. Add BP medication if BP not <140/90 mm Hg in 3 mo or if initial BP >160/100 mm Hg, with therapy individualized to take into account patient requirements and characteristics, such as age and need for drugs with specific benefits; <130/80 if diabetic.
Lipid management	Primary goal: LDL-C ≤70 mg/dL. Secondary goal: HDL-C >40 mg/dL and TG <200 mg/dL	If LDL-C elevated, rule out secondary causes via liver function tests, thyroid function tests, and urinalysis. Begin Therapeutic Lifestyle Changes (diet: saturated fat <7% of calories, cholesterol <200 mg/d, carbohydrates 55% of calories, protein 15% of calories, polyunsaturated fat up to 10% of calories, monounsaturated fat up to 20% of calories; weight management; and increased physical activity; also consider increased soluble fiber (10-25 g/day) and plant stanols/sterols (2 g/day) to enhance LDL lowering in all patients. Assess fasting lipid profile. In post-MI patients, lipid profile may take 4-6 wk to stabilize. Add drug therapy according to the following guide: LDL-C >100 mg/dL—Add drug therapy to diet Drug selection modified according to TG level: TG <200 mg/dL—Statin TG >200 mg/dL—Consider combined therapy with statin plus either niacin or fibrate If LDL goal not achieved, consider combination drug therapy.
Physical activity	30 min of moderate physical activity on most, if not all, days of the week	Assess risk, preferably with exercise test, to guide prescription. Encourage a minimum of 30-60 min of moderate-intensity dynamic exercise 3-4 times/wk as well as increased physical activity in daily life. Maximum benefit from 5-6 h/wk. Advise medically supervised programs for moderate- to high-risk patients.
Weight management	BMI <25 kg/m^2, waist circumference <40 inches for men and <35 inches for women; at a minimum, no increase in weight	Start intensive diet and appropriate physical activity intervention, as outlined here, in patients >120% of ideal body weight for height. Emphasize the need for weight loss in patients with hypertension, elevated TG, or elevated glucose levels.
Glucose control	Near normal fasting glucose/HbA1C	First-step therapy: weight reduction and exercise; Second-step therapy: oral hypoglycemic agents; Third-step therapy: insulin
Menopause		Combined estrogen plus progestin should not be used to prevent CVD in postmenopausal women.
Antioxidants		Antioxidant supplements should not be used to prevent CVD pending trial results.
Psychosocial	Evaluate for depression/anxiety disorders. Assess structural/functional support.	Refer to programs/activities that will enhance social support and refer/treat depression/anxiety. Focus on management of overall stress and specific situations.

continued

Table 9–14 Guide to Cardiovascular Disease Risk Reduction for Patients with Coronary and Other Vascular Disease or Diabetes—cont'd

Risk Intervention	Goal	Recommendations
Antiplatelet agents/ anticoagulants	Unless contraindicated, start aspirin at 80-325 mg/d. Start clopidogrel if patient is intolerant to aspirin.	Manage warfarin to international normalized ratio of 2-3.5 for post-MI patients unable to take aspirin. Consider warfarin in patients with severe LVD.
Angiotensin-converting enzyme inhibitors (ACEI)/ angiotensin-receptor blockers		Start as soon as possible after MI in stable patients if hemodynamics tolerate. Use angiotensin-receptor blockers if intolerant to ACEI.
β-Blockers		Start in post-MI patients and continue indefinitely if hemodynamics tolerate.

BMI, body mass index; BP, blood pressure; EF, ejection fraction; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol; LV, left ventricular; MI, myocardial infarction; TG, triglycerides.
Adapted and modified from Smith SC Jr, Allen J, Blair SN, et al: AHA/ACC guidelines for secondary prevention for patients with coronary and other atherosclerotic vascular disease: 2006 update: Endorsed by the National Heart, Lung, and Blood Institute. Circulation 2006;113:2363-2372.

the WHS study findings. Aspirin therapy reduced the risk of myocardial infarction (RR 0.76, 95% CI, 0.62 to 0.95, $P = 0.01$) and there was no reduction in stroke endpoints among men and women (RR 0.97, 95% CI, 0.83 to 1.13, $P = 0.69$). However, in analyses that included only women that used combined data from the Women's Health Study, the Hypertension Optimal Treatment (HOT) study, and the Primary Prevention Project, aspirin therapy was associated with a significant 19% reduction in risk of stroke (RR 0.81; 95% CI, 0.69 to 0.96; $P = 0.01$), but no reduction in risk of myocardial infarction (relative risk, 0.99; 95% CI, 0.83 to 1.19; $P = 0.95$).

Future Questions About Aspirin Therapy

Although the benefits of aspirin use for secondary prevention are solid, in primary prevention, the evidence supports only benefit in men, and among women older than the age of 65. The Preventive Services Task Force[322] and the American Heart Association[120] recommend aspirin for adults whose 10-year risks of a first coronary event are >6% and 10%, respectively. Aspirin should be used in most patients with cardiovascular disease.

Because differing doses of aspirin have been used in different trials, the correct dose for CHD prevention remains to be elucidated. Whether particular subgroups—diabetic, hypertensive—have different benefits from aspirin therapy also needs to be assessed. Antiplatelet agents such as ticlopidine and clopidogrel may be used in patients with aspirin allergy or intolerance.

β-Blockers

The role for β-blockers in secondary prevention after myocardial infarction has been long established[74] with important benefits post-myocardial infarction[323-326] and in the setting of acute myocardial infarction.[327,328] Primary prevention data regarding primarily β-blockers pertain to the treatment of hypertension, a major risk factor for cardiovascular disease. In the Puget Sound case-control study, the relative risk of hospitalization or death due to coronary heart disease was reduced by 29% in hypertensive heart patients treated with β-blockers compared with controls.[329] Also, in the British DHSS Hypertension Care Computing Project, men on β-blockers had lower mortality rates.[330] Although β-blockers are important for the treatment of hypertension and are also effective in preventing CVD, whether their effects are due to specific properties of β-blocker therapy including arrhythmia suppression, neurohumoral activity or to blood pressure management is undetermined.

ACE Inhibitors

ACE inhibitors (ACEI) are important agents for decreasing mortality after myocardial infarction,[331-333] particularly in patients with low ejection fraction (EF).[334] The benefits of ACEI in asymptomatic patients post-myocardial infarction with EF <40% were reported by the SAVE study, wherein long-term administration of captopril was associated with a 19% risk reduction in mortality.[93] Subsequently, the Heart Outcomes Prevention Evaluation (HOPE) Study demonstrated that the benefit of ACE inhibitors could be extended to patients with coronary heart disease and diabetes without left ventricular dysfunction.[80]

In primary prevention studies, ACE inhibitors have not been shown to be superior to other medical agents for the reduction of hypertension. For example, in the Antihypertensive and Lipid Lowering Treatment to Prevent Heart Attack (ALLHAT) Trial,[87] ACE inhibitors, calcium channel blockers, and diuretics showed similar effects on blood pressure management.

PRACTICE OF PREVENTIVE CARDIOVASCULAR DISEASE

Because worldwide the prevalence of CVD continues to rise, particularly in the developing world, strategies aimed at controlling this epidemic must target populations to achieve substantial reductions in disease burden. According to NHANES

data, in the United States alone, it is estimated that among those persons without a history of MI or stroke, but two or more inadequately controlled CVD risk factors, the population-attributable risk of CVD is 14% (approximately 17% of the U.S. population) and the annual cost is 13.2 billion dollars.[335] This cost is similar to that incurred by those individuals who already have a history of CVD. The cost of inadequate primary and secondary preventive efforts for CVD represents 30.1 billion dollars or 3% of the health care budget. Because these data do not take into account diabetes, this number may be an underestimate. In England, it is also estimated that if aggressive treatment strategies were instituted for those persons with a >20% 10-year Framingham Cardiovascular risk, major CVD events would be reduced by 34%.[336]

The effectiveness of any preventive medicine practices is highly dependent on population size and the number of targeted risk factors. A number of studies suggest that gain in years of life-expectancy is higher at younger ages, for male sex, and with treatment of those persons with risk factor clustering.[337] Tables 9–13 and 9–14 present information on the prevention of CVD for different patient categories. To reduce the staggering burden of CVD, efforts aimed at (1) understanding and improving barriers related to population and care-giver education about CVD and (2) uniform adherence to recommended therapy are warranted. These efforts must be coupled with community-based programs that incorporate nonphysician caregivers as well as continued risk factor research efforts in all populations.

Chapter 10

Non ST-Elevation Acute Coronary Syndromes

Stephen D. Wiviott and Robert P. Giugliano

CHAPTER CONTENTS

In this chapter we have drawn from evidence-based guidelines, have adopted the standard classification schemas used to grade the level of recommendation and strength of supportive evidence, and have provided updated information from the literature.[1-5] Because many of the supportive studies focused on a single comparison (e.g., drug X versus drug Y or drug X versus placebo) rather than comparisons of complex treatment strategies, and because the elderly and women are generally under-represented in published clinical trials, the reader should consider the impact of generalizing such results from specific studies to their patients.

Integrative Risk Assessment

Many attempts have been made to integrate clinical predictors and to objectify the assessment of the probability of adverse outcomes in different patient populations using multivariable analysis. Efforts have been made to incorporate physiologic, laboratory and demographic characteristics of patients into risk scores such as the Thrombolysis in Myocardial Infarction (TIMI) risk score for unstable angina/non ST-segment elevation myocardial infarction (UA/NSTEMI). Other scores derived from clinical trials[6,7] and registries[8-10] were developed to assess the risk of patients with non ST-segment elevation—acute coronary syndrome (NSTE-ACS) and to help identify patients most likely to benefit from aggressive therapy. An analysis comparing three risk scores (the TIMI, PURSUIT and GRACE scores, Table 10–1)[11] concluded that all three demonstrated good predictive accuracy for death or MI. The TIMI Unstable Angina Risk Score has been found to be useful in the prediction of angiographic severity and the extent of coronary artery disease,[12] including greater intracoronary thrombus burden and impaired flow.[13] Patients with higher TIMI risk scores derive greater benefit from aggressive antithrombotic strategies[14,15] and an early invasive strategy of angiography and coronary intervention.[16]

ANTI-ISCHEMIC MEDICATIONS

Management of UA/NSTEMI should be directed toward the dual goals of relief of the symptoms of myocardial ischemia and prevention of the severe short- and long-term sequelae that include recurrent MI, congestive heart failure, and death. Therapeutic efforts should be focused intensely on therapies that achieve both of these goals. A multi-faceted and continuously updated approach to the management of patients with NSTE-ACS may be necessary. For instance, a medication such as nitroglycerin, that may be used on the first encounter with a patient with ongoing ischemic chest pain to provide symptomatic relief, may be replaced with agents, such as angiotensin-converting enzyme inhibitors, that are expected to modify long-term risk. Patients for whom initial, intensive pharmacologic therapy does not produce relief of ischemic symptoms should be considered as candidates for early cardiac catheterization and revascularization (or ischemic relief with mechanical therapies such as intra-aortic balloon counterpulsation). For the majority of patients with NSTE-ACS, relief of ischemic symptoms can be achieved with pharmacologic measures.

Myocardial ischemia is a consequence of an imbalance in myocardial oxygen supply and demand. In most cases of UA/NSTEMI, the principal cause of this imbalance is abrupt reduction of blood flow resulting from nonocclusive coronary thrombosis.[17] For this reason, mainstays of therapy for UA/NSTEMI include antithrombotic and antiplatelet therapies, and coronary revascularization.[1] Revascularization may not always be immediately available, practical, safe or appropriate, and pharmacologic management of myocardial oxygen demand (MVO_2), and to a lesser extent supply, may result in relief of symptoms. The principal components of MVO_2 are heart rate, myocardial contractility, and wall stress.[18] Controlling and reducing these factors helps to improve the balance and relieve angina. Major classes of antianginal therapy include nitrates, β-adrenergic receptor antagonists (β-blockers), and calcium channel blockers. Morphine sulfate has mixed effects that reduce oxygen demand and angina.

Nitrates

The use of nitrates in NSTE-ACS is based on physiologic principles and expert consensus.[1] Nitroglycerin should be used in UA/NSTEMI for the rapid relief of ischemia and

Table 10–1 Integrative Clinical Risk Scores for Unstable Angina/Non ST-Segment Elevation Myocardial Infarction

Score	Features	Comments
TIMI[6]	Age ≥65, ≥3 cardiac risk factors, aspirin use in last 7 days, known CAD (previous stenosis ≥50%), recurrent angina in last 24 h, ST-segment deviation, elevated markers of necrosis	Sum of number of features (1 point for each)
PURSUIT[7]	Age by decade, sex, worst CCS class in last 6 weeks, signs of heart failure, ST-depression	Weighted score based on different point total (ranging from 0-14) for each feature
GRACE[9]	Age, heart rate, systolic BP, creatinine, Killip class, cardiac arrest, elevated markers, ST-segment deviation	Weighted score based on different point total (ranging from 0-91) for each feature.

BP, blood pressure; CAD, coronary artery disease; CCS class, Canadian Cardiovascular Society Anginal Class.

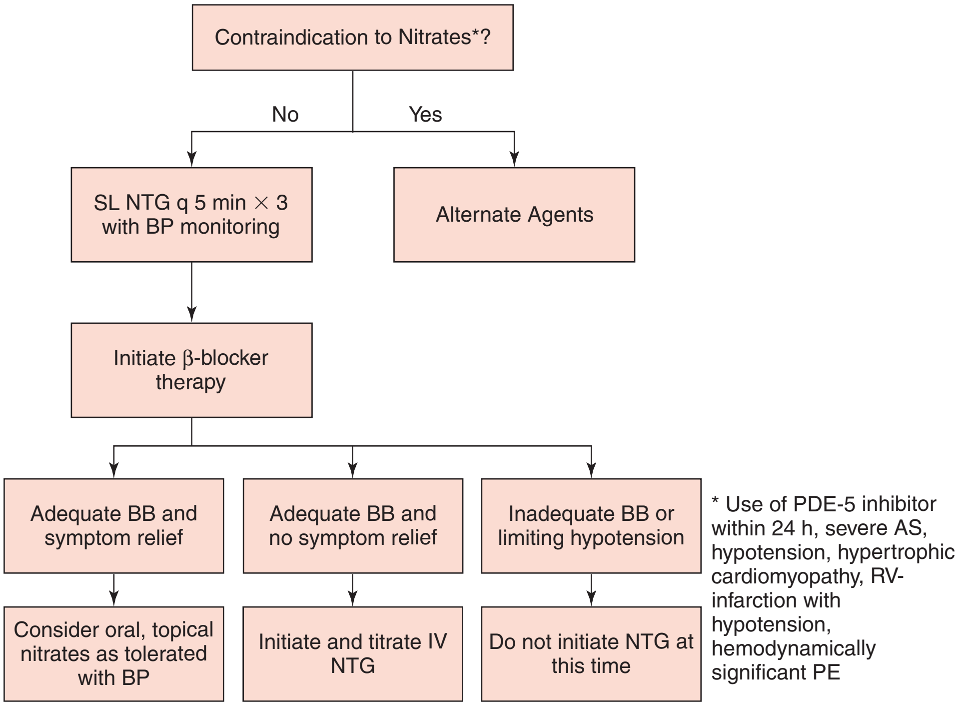

Figure 10–1 Schematic for early use of nitrates in acute coronary syndrome. AS, aortic stenosis; BB, β-blocker; BP, blood pressure; NTG, nitroglycerin; PE, pulmonary embolism; RV, right ventricular; SL, sublingual.

ischemic-related symptoms including angina and congestive heart failure (Fig. 10–1). In suitable patients, nitrate administration should begin with sublingual administration of 0.4 mg (tablets or spray) given at 5-minute intervals up to three doses. Intravenous nitroglycerin treatment may be initiated in patients with refractory symptoms and without hypotension despite adequate doses of β-blocker.[1] Intravenous nitroglycerin is initiated at 5 to 10 mcg/min of continuous infusion and may be titrated upward at 3- to 5-minute intervals until 20 mcg/min is reached. If this dose is tolerated without hypotension and anginal symptoms persist, larger titration steps of 20 mcg/min are usually well tolerated. Titration should cease when symptom relief is achieved, when hypotension ensues, or when a maximum dose of approximately 200 to 300 mcg/min is reached. Tolerance to the anti-ischemic effects of nitrates may develop within 12 to 24 hours and can be ameliorated by nitrate-free intervals. If symptoms do not allow for nitrate-free intervals, increasing the dosing may be effective. Despite tolerance, abrupt removal of nitrates may result in recurrent ischemia,[19] and discontinuation of high-dose intravenous nitrates should be performed by stepped down-titration.

The pharmacologic effects of nitrates, predominantly venodilation and reduction of ventricular preload, may be detrimental to patients who are highly dependent on ventricular preload for the maintenance of cardiac output and can result in substantial hypotension. Nitrates should generally be avoided, or used with considerable caution, in patients with right ventricular infarction, severe aortic stenosis, hypertrophic cardiomyopathy, or pulmonary embolism. Nitrates are contraindicated in patients who have used phosphidiesterase-5 (PDE-5) inhibitors (sildenafil, tadilafil, vardenafil) within the preceding 24 to 48 hours[1] because of exaggeration and prolongation of nitrate effects from the inhibition of the breakdown of cyclic GMP, which modulates the vasodilator effects of nitrates. The combination of PDE-5 inhibitors and nitrates has been reported to be associated with severe hypotension, myocardial ischemia, and death.[20,21]

β-Adrenergic Receptor Blockers

Clinical trial data for the use of β-blockers specifically in UA/NSTEMI are sparse. A systematic review of the accumulated trial data suggests that β-blockers reduce the risk of progression to MI in NSTE-ACS.[22] In contrast, a large body of randomized controlled trial data suggests benefits in reducing recurrent MI and death by early β-blocker use in STEMI.[23-25] Therefore, the evidence for the use of β-blockers in NSTE-ACS results largely from extrapolation from STEMI trials and physiologic principles.

Based on these data, β-blockers should be initiated in the treatment of UA/NSTEMI as early as possible for patients without contraindications. β-blockers should be used cautiously or avoided in patients with new or decompensated congestive heart failure or significant first-degree atrioventricular block, and withheld in patients with severe bradycardia, second-, or third-degree AV block without a pacemaker, and selective β-blocker patients for whom NSTE-ACS is secondary to profound catecholamine excess, such as pheochromocytoma or cocaine use. For patients with reactive airways disease, the use of a cardioselective (β_1) agent is recommended. Initial therapy for patients with evidence of ongoing ischemia should be intravenous β-blocker such as metoprolol 5 mg every 5 minutes up to three doses as tolerated by heart rate and blood pressure. After initial IV dosing, oral β-blocker therapy should be initiated early to avoid a rebound effect between the offset of the IV agent and the onset of the oral agent.

Calcium Channel Antagonists

Dihydropyridine calcium channel blockers have predominantly peripheral vasodilatory actions, whereas nondihydropyridine CCBs have significant SA- and AV-node depressant effects as well as possible myocardial depressant effects with lesser amounts of peripheral vasodilation (see Chapter 5). Coronary vasodilation appears to be similar among agents.[1] The predominant clinical role for CCBs has been in the control of hypertension. However, the physiologic properties of arterial vasodilation, heart rate slowing, and contractility reduction favorably alter myocardial oxygen balance. Because of these differences in properties, the two types of CCBs will be considered separately.

The dihydropyridine CCBs cause a reflex tachycardia in the absence of adequate β-blocker therapy, a mechanism that may underlie apparent adverse effects of these agents on patients with NSTE-ACS.[26,27] In contrast to the dihydropyridines, diltiazem and verapamil are heart rate slowing agents and appear not to increase rates of ischemic events in patients with UA/NSTEMI. Concerns, however, have been raised that myocardial depressant effects may increase the risk of heart failure. The relationship of the nondihydropyridine CCBs to congestive heart failure is somewhat controversial. In retrospective analyses of calcium channel blocker trials, there has been evidence for increased rates of congestive heart failure and an increase in the mortality rate in patients with diminished ejection fraction.[28,29] These findings, however, are counterbalanced by studies that show beneficial effects of CCBs in patients with heart failure who are treated concurrently with ACE inhibitors.[30]

In summary, calcium channel blockers reduce symptomatic ischemia. Short-acting dihydropyridine CCBs have not been shown to improve cardiac outcomes and may result in worse outcomes in the absence of β-blockers. Newer, longer acting dihydropyridine CCBs have not been studied in NSTE-ACS. Nondihydropyridine calcium channel blockers are antianginal, do not result in harm, and may improve outcomes in patients with NSTE-ACS, especially those patients without left ventricular dysfunction. Therefore, nondihydropyridine calcium channel blockers can be considered for use in patients who do not tolerate β-blockers.[1]

ANTIPLATELET AGENTS

Antiplatelet agents represent the cornerstone of therapy for patients with NSTE-ACS. Pharmacologic inhibition of platelet function can be achieved by interfering with a number of processes that include inhibition of cyclooxygenase (COX), phosphodiesterase, adenosine diphosphate (ADP), thromboxane, serotonin, platelet adhesion, or platelet aggregation, and has led to the development of numerous platelet inhibitors (Table 10–2), of which aspirin, the thienopyridines, and the intravenous glycoprotein (GP) IIb/IIIa inhibitors have been studied most extensively.

Table 10–2 Classification Scheme of Select Antiplatelet Agents

Arachidonic Acid Inhibitors

Cyclooxygenase (COX) inhibitors—aspirin, indobufen, triflusal, nonsteroidal anti-inflammatory agents, sulfinpyrazone

Non-COX inhibition of arachidonic acid

Phosphodiesterase Inhibitors—dipyridamole, pentoxifylline, cilostazol, trapidil

Other—omega-3 fatty acids, eicosanoids (prostacyclin, prostaglandin analogs)

$P2Y_{12}$ Inhibitors

Thienopyridines (ADP antagonists)—ticlopidine, clopidogrel, prasugrel

ATP derivative—cangrelor

Cyclopentyltriazolopyrimidine (CPTP)—AZD6140

Inhibitors of Platelet Adhesion

von Willebrand factor (vWF) inhibitors—aurintricarboxylic acid (ATA), peptide fragments derived from the human plasma vWF-GP1b-IX binding domain, monoclonal antibodies to vWF

GP1b-IX Inhibitors

Platelet Glycoprotein IIb/IIIa Receptor Blockers

Intravenous

Abciximab, tirofiban, eptifibatide

Oral

Xemilofiban, sibrafiban, orbofiban, lotrafiban, roxifiban, cromofiban

Drugs with Secondary Antiplatelet Activity

Direct thrombin inhibitors, heparin, nitrates, fibrates, calcium-channel antagonists, and others

Aspirin

Several small- to medium-sized clinical trials that compared aspirin with placebo in NSTE-ACS demonstrated approximately a 50% reduction in death or MI (Fig. 10–2). These data support the class I indication in the 2002 ACC/AHA UA/NSTEMI Guideline Update to begin aspirin immediately and to treat indefinitely on establishment of the diagnosis of NSTE-ACS.[3] Because aspirin is one of the most inexpensive drugs available, with a known and generally safe profile, it is unlikely that future placebo-controlled studies will be undertaken, and thus aspirin is likely to remain the first-line antiplatelet agent in NSTE-ACS for the foreseeable future.

Two areas of intense debate and ongoing research regarding aspirin use are the issues of optimal dose and aspirin resistance. Despite its long history, the optimal dose of aspirin remains to be definitively established. Increased doses have been associated with more bleeding, yet the relationship of the dose with efficacy is less clear.[31] A dose of 40 mg was found to achieve maximal inhibition once steady state has been achieved, although doses of >160 mg are needed to produce a rapid clinical antithrombotic effect, and doses of <75 mg daily have not been well studied in clinical trials.[32-35] A meta-analysis by the Antiplatelet Trialists' Collaboration demonstrated no increase in benefit in aspirin across maintenance doses ranging from 75 mg to 1500 mg daily, whereas gastrointestinal bleeding *was* increased at doses above 300 mg daily.[31] Two nonrandomized subgroup analyses[36,37] comparing different doses of aspirin confirmed that higher doses of aspirin were associated with an increased risk of bleeding and no apparent reduction in ischemic complications. A random effects multivariate regression model concluded that efficacy of aspirin did not increase at higher doses; in fact, the point estimates suggest less benefit at higher doses.[38]

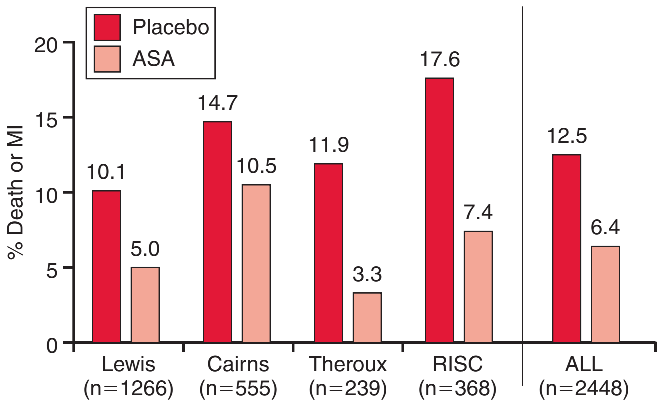

Figure 10–2 Placebo-controlled trials with aspirin in patients with non ST-segment elevation acute coronary syndrome (NSTE-ACS). Aspirin was associated with a 50% reduction in death or MI compared with placebo. (From Braunwald E, Antman EM, Beasley JW, et al: ACC/AHA guideline update for the management of patients with unstable angina and non ST-segment elevation myocardial infarction—2002: Summary article: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee on the Management of Patients with Unstable Angina]. Circulation 2002; 106(14):1893-1900.) (With permission).

An inadequate response to aspirin, sometimes termed "aspirin resistance," has been described for more than a decade.[39] Controversy persists, however, regarding how this should be defined and what methodology should be used to measure the antiplatelet effect of aspirin.[40] Several studies have shown that resistance to aspirin is associated with worse clinical outcomes across a broad range of patients with stable and unstable CAD, peripheral vascular disease, and stroke (Table 10–3). There are multiple possible explanations for hyporesponsiveness to aspirin, including clinical factors (e.g., noncompliance, failure to absorb the drug), cellular factors (e.g., failure to suppress COX, increased platelet activation), and genetic polymorphisms involving key enzymes (e.g., COX-1) or receptors (GP-IIIa). Three clinical factors that have been associated with hyporesponsiveness to enteric-coated aspirin 81 mg are younger age, increased weight, and history of MI.[41] Increasing the dose of aspirin may increase the antiplatelet response in such patients; whether this improves clinical outcomes has yet to be demonstrated.

Guidelines for patients with NSTE-ACS[1,42] or who are undergoing PCI[43] recommend an initial dose of 162 mg to 325 mg. Post-stenting, the recommended dose is 325 mg for at least 1 month (bare metal stent), 3 months (sirolimus-coated stent), or 6 months (paclitaxel-coated stent).[43] To decrease the risk of bleeding, the aspirin dose may be reduced to 81 mg to 162 mg.[43]

Thienopyridines

Thienopyridines act by irreversibly blocking the $P2Y_{12}$ receptor on the platelet surface, thereby interrupting platelet activation and aggregation.[44] When administered at the currently approved doses (clopidogrel 75 mg daily, ticlopidine 250 mg twice daily), these agents achieve at steady state a moderate level of median platelet inhibition (20% to 35%)[45,46] as assessed by using 20 μmol/L ADP as the agonist, compared with the intravenous GP IIb/IIIa inhibitors (80% to 95%).[47] An earlier effect on platelet function occurs with administration of a loading dose,[48] although the absolute degree of platelet inhibition is marginally increased with higher doses once steady state is achieved. Bleeding time increases roughly twofold and normalizes 10 days after the last dose, consistent with the life span of the platelet. The thienopyridines also have

Table 10–3 Clinical Impact of Resistance to Aspirin

Patient Cohort	Aspirin Dose	Duration of Follow-up	Endpoint	Result (resistant vs. responsive groups)
Stroke[1]	1500 mg	24 months	Stroke/MI/vascular death	10-fold ↑
PVD[2]	100 mg	18 months	Arterial occlusion	87% ↑
CVD/CVA/TIA[3]	100 mg	>60 months	Recurrent CVA/TIA	34% vs. 0%
HOPE subgroup[4]	75-325 mg	5 years	MI/stroke/CV death	1.8-fold ↑ (1st vs. 4th quartile)
CVD[5]	325 mg	~2 years	Death/MI/CVA	3-fold ↑

a number of other effects that are not fully characterized on platelet function beyond inhibition of ADP-induced aggregation, such as inhibition of platelet activation, reduction in fibrinogen levels and blood viscosity, and less erythrocyte deformability and aggregability. If rapid onset of platelet inhibition is required (e.g., at the time of intracoronary stenting), a loading dose should be administered (Table 10–4).

Based on the CAPRIE study that demonstrated about a 9% reduction compared with aspirin in vascular death, MI, or stroke among 19,185 patients with atherosclerotic vascular disease, clopidogrel was given a class I recommendation for use in patients with NSTE-ACS who have hypersensitivity or major gastrointestinal intolerance to aspirin.[49] The combination of aspirin plus clopidogrel was compared with aspirin alone in the CURE trial of 12,562 patients with NSTE-ACS treated for 3 to 12 months.[50] Clopidogrel reduced the composite of death, MI, and stroke by 20% compared with placebo, with benefit evident both in the first 30 days and over the ensuing average follow-up of up to 9 months.[51] There was also a 38% increase in the rate of bleeding overall, with patients who underwent CABG within 5 days of the discontinuation of clopidogrel at particular risk (53% increased rate). In a secondary analysis (PCI-CURE) of patients in the CURE trial who underwent percutaneous coronary intervention (PCI), patients pretreated with clopidogrel (for a median of 10 days) had a reduction in both early (30-day) and long-term cardiovascular events.[52] As a result of these findings, the 2002 ACC/AHA UA/NSTEMI guidelines[3] considered the use of clopidogrel in addition to aspirin to have a class I indication for patients with NSTE-ACS who are undergoing an early noninterventional or interventional approach and who are not at risk for major bleeding. For patients for whom elective CABG is planned, the drug should be withheld for 5 to 7 days to reduce the risk of perioperative bleeding and transfusion.

Several important issues regarding treatment with clopidogrel remain controversial and continue to be studied: identification of the optimal loading dose and timing of initiation of clopidogrel, duration of therapy, and clinical relevance of clopidogrel resistance. Without a loading dose, clopidogrel achieves steady-state levels of platelet inhibition in 4 to 7 days. Administration of various loading doses has been studied, with reductions in the time to steady state of 12 to 48 hours (for 300 mg) to 2 to 6 hours (for 600 to 900 mg). Data from the CREDO trial[53] suggested that a minimum of 12 to 15 hours between the loading dose and PCI was required for a 300 mg load to demonstrate clinical benefit (compared with no load), whereas the ARMYDA-2 study[54] showed better outcomes with 600 mg versus 300 mg when clopidogrel was initiated 4 to 8 hours before PCI (Fig. 10–3). The decisions to load or not before PCI, and with what dose, are clinically important because of the trade-off between potential benefit (if a sufficient load is administered long enough before PCI) and risk of bleeding (if the patient needs to undergo CABG surgery). Given the limited amount of available clinical data (both CREDO and ARMYDA-2 were relative small trials, the latter had an unusually high event rate in the 300 mg clopidogrel arm), it is not surprising to find divergent recommendations in the two PCI guidelines released in 2005[43,55,56] and divergent practice patterns in Europe and North America. The European Society of Cardiology guidelines recommend 300 mg of clopidogrel ideally administered the day before PCI and 600 mg administered if PCI is being performed within 6 hours.[55] Meanwhile, the ACC/AHA/SCAI guideline takes a more conservative position, recommending that a 300-mg dose be administered at least 6 hours before the procedure, noting that the clinical benefit and safety of higher doses of clopidogrel are not well established.[43]

The duration of treatment with clopidogrel is an important clinical issue because the drug is costly to administer relative to aspirin and is associated with an increased risk of bleeding. The primary endpoint in the CURE study was at 30 days and a secondary endpoint was at the end of the trial (mean 9 months, range 3 to 12 months). The AHA/ACC NSTE-ACS guideline[3] currently gives a class Ia indication to a treatment duration of 1 month, with 9 months' duration considered class Ib. After PCI, the optimal duration of clopidogrel therapy depends on the risk of subsequent thrombosis, which itself is a related to the type of intervention, use of an intracoronary stent, and the type of drug-eluting stent (if any) placed (Table 10–5). These recommendations are based largely on observational data and randomized trial protocols (as opposed to randomized comparisons); further studies are

Table 10–4 Standard Dosing Regimens for Frequently Used Antiplatelet Agents

Drug	Loading Dose	Maintenance Dose
Aspirin	162-325 mg PO* or p.r. 150-500 mg IV	75-325 mg daily PO indefinitely
Thienopyridienes		
Clopidogrel	300-600† mg PO	75 mg PO daily for ≥ 30 d
Ticlopidine	500 mg PO	250 mg twice PO daily for ≥ 30 d
Glycoprotein IIb/IIIa Blockers		
Abciximab	0.25 mg/kg IV	0.125 mcg/kg/min IV for 12-24 h
Eptifibatide	180 mcg/kg IV‡	2§ mcg/kg/min IV for 18-72 h
Tirofiban	0.4‖ mcg/kg/min IV × 30 m	0.1‖ mcg/kg/min IV for 48-96 h

*Preferably chewed to achieve more rapid absorption.
†Some studies have investigated 900 mg but few, if any, clinically meaningful differences have been reported between 600 mg and 900 mg.
‡In patients scheduled to undergo PCI, a second bolus of 180 mcg/kg IV is given 10 minutes after the first bolus.
§1 mcg/kg/min if the estimated creatinine clearance is <50 mL/min.
‖The loading and maintenance infusion rates should be reduced by one half if the estimated creatinine clearance is <30 mL/min.

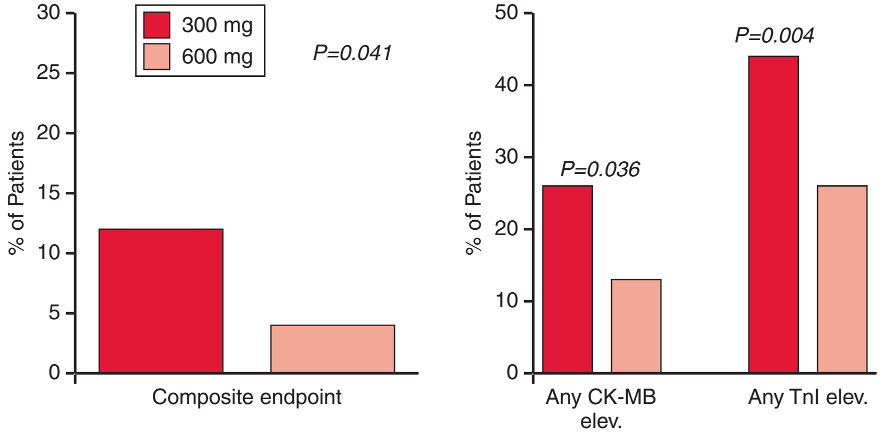

Figure 10–3 Main results of the ARMYDA-2 trial. ARMYDA-2[54] compared 600 mg with 300 mg clopidogrel administered 4 to 8 hours before PCI in 255 patients with known CAD. The rate of the primary composite endpoint of death, MI, or target vessel revascularization up to 30 days post-PCI, as well as the rates of elevated biomarkers of myonecrosis post-PCI, were reduced with clopidogrel 600 mg. The rate of MI following PCI with 300 mg was unexpectedly higher than has been reported in other similar studies. CAD, coronary artery disease; CK-MB elev., creatine kinase-myocardial band elevation; MI, myocardial infarction; PCI, percutaneous coronary intervention; TnI elev., troponin I elevation. (With permission).

Table 10–5 Minimum Duration of Recommended Uninterrupted Clopidogrel Therapy in Patients with Non ST-Segment Elevation-Acute Coronary Syndrome

Patient Scenario	Minimum Recommended Duration
NSTE/ACS managed without stenting	1 month
Bare metal stent	1 month*
Sirolimus-coated stent	3 months
Paclitaxel-coated stent	6 months
Stent brachytherapy	Indefinitely

*2 weeks acceptable if patient at substantially increased risk of bleeding.
NSTE-ACS, non ST-segment-acute coronary syndrome.
Modified from Smith SC, Jr, Feldman TE, Hirshfeld JW, Jr, et al: ACC/AHA/SCAI 2005 Guideline Update for Percutaneous Coronary Intervention—summary article: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (ACC/AHA/SCAI Writing Committee to Update the 2001 Guidelines for Percutaneous Coronary Intervention). Circulation 2006;113:156-75.

awaited. Other observational data have identified a strong link between the interruption of antiplatelet therapy after ACS[57] and an increased risk of adverse outcomes including stent thrombosis.[58] Thus, the threshold to hold or terminate antiplatelet therapy early should be high (e.g., life-threatening bleeding or need for high-risk emergency surgery).

The CHARISMA trial evaluated the usefulness of clopidogrel in addition to aspirin for a median of 28 months in high-risk patients with stable cardiovascular disease across a wide range of patients.[59,60] Although there was no difference in the primary endpoint of cardiovascular death, MI, or stroke between the clopidogrel plus aspirin group (6.8%) and the placebo plus aspirin group (7.3%, $P = 0.22$), the secondary endpoint (which also included rehospitalization for ischemic events) was reduced by 8% ($P = 0.04$) with dual antiplatelet therapy.[61] The secondary prevention subgroup (approximately 80% of patients enrolled had documented preexisting cardiovascular disease) had a 12% ($P = 0.046$) lower incidence of the primary composite, whereas the remainder of asymptomatic patients (primary prevention) had a 20% excess ($P = 0.20$), including a higher rate of cardiovascular death (3.9% versus 2.2%, $P = 0.01$). In the overall study population, severe bleeding tended to be more frequent in the clopidogrel group (1.7% versus 1.3%, $P = 0.09$). Thus, longer-term clopidogrel, in addition to aspirin, appeared beneficial in secondary prevention of ischemic complications among patients with established cardiovascular disease (with a trend toward more severe bleeding), but was not useful and potentially harmful in asymptomatic patients (primary prevention).

Failure of clopidogrel to achieve the desired pharmacologic effect is another area that is undergoing intense research. Several studies of platelet function have documented the variable pharmacologic response to standard dose clopidogrel among groups of individuals. Depending on the method, timing, and definition of "resistance," between 5% and 30% of patients do not achieve the expected pharmacologic response to clopidogrel.[62,63] This may be overcome, in part, by either readministration of a 300-mg loading dose to patients who were chronically taking 75 mg daily,[64] or by loading initially with 600 mg in clopidogrel naïve patients.[65] This may come at a cost of increased bleeding risk particularly in patients who subsequently require urgent CABG. Similar to the observations described with resistance to aspirin, several small studies have suggested that hyporesponders to clopidogrel are at increased risk of ischemic complications, including stent thrombosis.[65-67] Pending confirmation of these findings in larger datasets, two important questions need to be answered: (1)should antiplatelet effect be routinely measured—and if so—how?; (2) how can clopidogrel resistance be minimized or managed?[68] Among the possible options to achieve higher degrees of inhibition of platelet aggregation are intravenous GP IIb/IIIa inhibitors and newer inhibitors of the $P2Y_{12}$ receptor (see Antiplatelet Drugs in Development).

Figure 10–4 Intravenous GP IIb/IIIa inhibitors in patients with NSTE-ACS undergoing percutaneous coronary intervention (PCI). The outcome of death or myocardial infarction in six clinical trials of intravenous GP IIb/IIIa inhibitors that involve more than 1000 patients is shown. (From Braunwald E, Antman EM, Beasley JW, et al: ACC/AHA 2002 Guideline Update for the Management of Patients with Unstable Angina and Non ST-Segment Elevation Myocardial Infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee on the Management of Patients with Unstable Angina]. Available at: http://www.acc.org/clinical/guidelines/unstable/unstable/pdf.) (With permission).

Intravenous Glycoprotein IIB/IIIA Blockers

The most potent inhibitors of platelet aggregation clinically available are the intravenous GP IIb/IIIa blockers. These agents inhibit the final common pathway of platelet aggregation, namely, the binding of fibrinogen or von Willebrand factor to the membrane GP IIb/IIIa integrin receptor, thus preventing the inducement of platelet aggregation by various platelet agonists. There are three intravenous GPIIb/IIIa blockers commercially available: abciximab (an irreversible monoclonal antibody), eptifibatide, and tirofiban (the latter two are reversible small molecules). Several oral GP IIb/IIIa blockers were studied in clinical trials; however, their development was halted after five consecutive phase III studies demonstrated an increase in mortality rate.[37,69] We will, therefore, focus the remainder of this section on the intravenous preparations.

Intravenous GP IIb/IIIa blockers were initially developed for use as adjuncts to PCI, and numerous clinical trials have demonstrated reductions in ischemic complications (particularly periprocedural MI) with their use. In six large trials of patients with NSTE-ACS who were undergoing PCI, the relative risks of death or MI at 30 days were reduced by 31% to 83% with the addition of intravenous GP IIb/IIIa inhibitors (Fig. 10–4).[1] It is estimated that intravenous GP IIb/IIIa inhibitors may reduce mortality by one third across a wide range of patients who were undergoing PCI.[70] These data support the current class Ia indication for intravenous GP IIb/IIIa blockers in patients with NSTE-ACS for whom an early invasive strategy is planned (Table 10–6).[1,42]

Among patients with NSTE-ACS who are *not* routinely scheduled to undergo coronary revascularization, a meta-analysis involving 31,402 patients demonstrated a smaller reduction in the odds of death or MI (9% [2% to 16%], $P = 0.015$) with addition of intravenous GP IIb/IIIa inhibitor therapy.[71] However, there was evidence for heterogeneity by drug because the largest trial (GUSTO-IV ACS[72]) with abciximab (which does not sustain a high degree of platelet inhibition beyond 12 hours) showed a directionally negative effect, whereas trials with the small molecule intravenous GP IIb/IIIa blockers revealed modest benefits. Furthermore, post-hoc analyses demonstrated greater benefit among patients who are at higher risk at baseline, as identified by an elevated baseline troponin[71] or higher TIMI Risk Score.[73]

Because there also is the potential for benefit of intravenous GP IIb/IIIa inhibition prior to PCI,[74] it would appear

Table 10–6 Guideline Recommendations Regarding Intravenous GP IIb/IIIa Blockers in Patients with Non ST-Segment-Acute Coronary Syndrome

Patients who are being managed with an early invasive strategy (i.e., plan for early diagnostic catheterization)
- With aspirin and heparin—Class Ia, evidence level A*
- With aspirin, heparin, and clopidogrel—Class IIa, evidence level B

Patients with who are being managed with an early conservative strategy (i.e., no plans for diagnostic catheterization)
- If continuing ischemia, elevated troponin, or other high-risk features—Class IIa, evidence level A†
- If none of the above present—Class IIb, evidence level A†

*European guidelines[42] emphasize this recommendation among patients with an elevated troponin or diabetes.
†Eptifibatide or tirofiban only. Abciximab is Class III (evidence level A).
Modified from references 1 and 42.

reasonable to begin therapy early ("upstream"), although this has not been rigorously proved. This is the central hypothesis being tested in a large international study known as EARLY ACS that is comparing upstream eptifibatide with placebo before angiography in patients with high-risk NSTE-ACS who are managed with an early invasive strategy.[75]

Several additional unanswered questions with regard to intravenous GP IIb/IIIa blockers are being explored in ongoing studies. Can other oral antiplatelet, intravenous antiplatelet, and/or more efficacious anticoagulant drugs be as effective as intravenous GP IIb/IIIa blockers? Is there still a need for multiple antiplatelet agents? These are increasingly interesting issues particularly as more potent oral agents are developed.

Mechanistic studies support the addition of intravenous GP IIb/IIIa blockers to aspirin and thienopyridines because the latter two agents are not sufficient to achieve the high-grade platelet inhibition that is associated with a reduction in clinical events in PCI. Results from clinical studies, however, are conflicting, and only one large study has been completed in patients with NSTE-ACS. In the TOPSTAR trial,[76] addition of an intravenous GP IIb/IIIa blocker to aspirin and clopidogrel (including preloading with 375 mg the day before PCI) was associated with a reduction in the composite of death, MI, or urgent target vessel revascularization at 9 months. Similarly, in the CLEAR PLATELETS study,[77] fewer periprocedural MIs were present with intravenous GP IIb/IIIa blockade, even when 600 mg clopidogrel was administered 2 to 6 hours before PCI. Meanwhile, intravenous GP IIb/IIIa blockers did not improve outcomes in studies of stable low-risk patients[78] and in diabetics[79] who underwent PCI when 600 mg clopidogrel was used as background therapy. Intravenous GP IIb/IIIa blockade plus unfractionated heparin was not superior to bivalirudin in a third trial.[80] More recently, among 2022 patients with NSTE-ACS who were undergoing PCI all of whom were preloaded with 600 mg of clopidogrel at least 2 hours before PCI, the GP IIb/IIIa inhibitor abciximab reduced ischemic complications by 25% in the ISAR-REACT 2 trial.[81] The benefit was seen only in patients with a positive troponin at baseline. There was an excess of thrombocytopenia but no difference in clinically important bleeding among patients treated with abciximab.

Preliminary results of the ACUITY Timing Trial,[82] which compared early administration of GP IIb/IIIa inhibition with initiation in the catheterization laboratory as needed in 9207 patients with NSTE-ACS, were presented at the 2006 ACC Scientific Sessions. The primary endpoint (net clinical benefit including death, reinfarction, ischemia leading to unplanned revascularization, major bleeding) was 11.7% in both groups, meeting the prespecified statistical criterion for non-inferiority. However, delayed GP IIb/IIIa inhibition was associated with a numerically higher rate (7.9% versus 7.1%) of the ischemic complications (death, reinfarction, ischemia leading to unplanned revascularization) compared with upstream use, and did *not* fulfill the non-inferiority criterion. Major bleeding was reduced by approximately 20% with delayed use of GP IIb/IIIa. In patients who were undergoing PCI and in higher risk patients (troponin elevated at baseline, TIMI Risk Score 5 to 7), upstream GP IIb/IIIa inhibition appeared to offer some protection against ischemic complications. As additional detailed analyses are performed and published, further insight into the optimal use and timing of GP IIb/IIIa inhibitors may modify the current guideline recommendations (see Table 10–6).

Antiplatelet Drugs in Development

Well into clinical development are three antiplatelet agents that are more potent than the currently available oral antiplatelet drugs. Prasugrel is a thienopyridine that potentially offers three major advantages over clopidogrel: (1) faster onset of action[83] (owing to prehepatic metabolism along the path for generation of the active metabolite compared with exclusively intrahepatic metabolism for generation of the active form for clopidogrel); (2) higher degree of ex-vivo platelet inhibition; and (3) less intrapatient variability (i.e., fewer hyporesponders). In pharmacodynamic studies, prasugrel achieved a higher degree of ex-vivo platelet inhibition of ADP-induced platelet aggregation compared with standard dose clopidogrel,[84] and was as effective in patients who were hyporesponsive to clopidogrel as were those who achieved the expected pharmacodynamic response. In a phase 2 dose-ranging study of patients who were undergoing PCI (JUMBO-TIMI 26),[85] prasugrel (40 to 60 mg loading dose, maintenance 7.5 to 15 mg daily) was associated with similar bleeding rates and less frequent target vessel thrombosis and recurrent ischemia. Prasugrel (60 mg loading dose, 10 mg maintenance) is currently being compared with clopidogrel in a phase 3 trial of patients with ACS who are undergoing PCI (TRITON-TIMI 38).

AZD6140 is an oral antiplatelet agent that is the first member of a new class of $P2Y_{12}$ receptor antagonists known as the cyclopentyltriazolopyrimidines.[83] In phase 2 dose-ranging trials, AZD6140 (90 to 180 mg twice daily.) achieved higher levels of ADP-induced inhibition than clopidogrel, did not increase bleeding, and at a dose of 180 mg twice daily was associated with numerically fewer cardiovascular ischemic complications.[86]

Cangrelor is an intravenous ATP derivative that can achieve 90% inhibition of platelet aggregation (similar to intravenous GP IIb/IIIa blockers) and has a plasma half-life of 5 minutes, with recovery of platelet function 20 minutes after cessation of infusion.[87] In a phase 2 trial of patients who were undergoing PCI, cangrelor and abciximab were associated with similar low rates of post-PCI ischemic complications; whereas cangrelor was associated with one half the number of bleeding events.[88]

ANTICOAGULANTS

Beginning with the expression of tissue factor and ending with the production of thrombin, the biologic complexity of the coagulation cascade has yielded a number of promising targets for anticoagulation therapy (Fig. 10–5).[209] Agents that inhibit the earlier portion of the cascade (e.g., tissue factor [TF] antibodies, TF/VIIa complex inhibitors, factor Xa inhibitors) are potent inhibitors of thrombin generation, whereas those that target more distally (e.g., direct thrombin inhibitors [DTIs]) derive most of their pharmacologic effect by inhibiting preexisting thrombin. Because of biologic redundancies and multiple feedback loops in the coagulation system, inhibition at one level of the cascade can have complex effects that make it difficult to predict the clinical response to these drugs. UFH had been the standard anticoagulant for decades, although extensive study over the past 15 years with low-molecular-weight heparins (LMWHs), DTIs, and inhibitors of factor Xa, are leading to updates of practice guidelines (see Chapter 5).

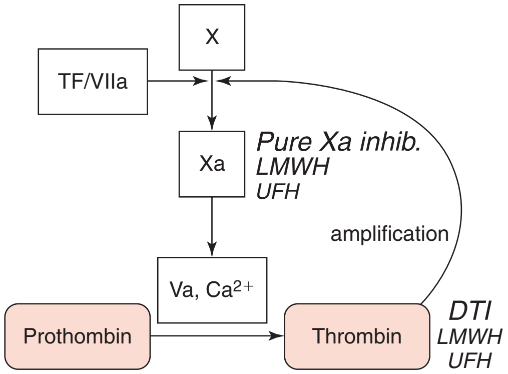

Figure 10–5 Activation of the coagulation cascade and platelet aggregation in patients with ACS. After disruption of a vulnerable plaque, tissue factor (TF) is exposed, complexes with factor VIIa, and initiates the coagulation cascade. Factor X is activated, and leads to the production of thrombin through its interaction with the prothrombinase complex (factor Va, factor Xa, calcium ion [Ca^{2+}]) on the membrane of activated platelets. Platelets may be activated via number of pathways—two of the more potent agonists are thrombin and adenosine 5′-diphosphate (ADP). The final common step to platelet activation is fibrinogen binding, which mediates platelet–platelet interaction. Unfractionated heparin (UFH) inhibits factor Xa and thrombin to a similar degree; whereas low-molecular-weight heparins (LMWHs) exert proportionally a greater effect on factor Xa, and direct thrombin inhibitors (DTIs) predominantly act only on thrombin. The larger font size indicates a qualitative greater effect at the position in the coagulation cascade shown. (Modified from Antman EM: The search for replacements for unfractionated heparin. Circulation 2001;103(18):2310-14.) (With permission).

Unfractionated Heparin and Low-Molecular-Weight Heparin

The optimal dose of unfractionated heparin (UFH) has not been rigorously established, however, several studies support a lower, weight-based dosing regimen[89] to improve the safety profile without apparent loss of efficacy (Table 10–7). UFH has a number of limitations (Table 10–8) that have led to the search for a replacement anticoagulant.

Unlike UFH, the LMWHs have a number of other advantages that include less nonspecific binding to proteins and platelets, less depletion of tissue factor pathway inhibitor, and greater inhibition of vWF. Furthermore, the better bioavailability and longer half-life permits subcutaneous dosing, thereby improving the ease of administration both in and out of hospital (see Table 10–8). Although more than a dozen different LMWH preparations have been developed, only two (enoxaparin and dalteparin) have been widely studied in patients with ACS.[90] Enoxaparin has a lower molecular weight (4200 versus 6000), slightly higher anti Xa:IIa ratio (3.8:1 versus 2.7:1), and greater inhibition of vWF compared with dalteparin. Both drugs are administered subcutaneously in a weight-based fashion in their maintenance dosing, whereas an intravenous bolus dose of 30 mg enoxaparin has also been studied in NSTE-ACS[91] and as an adjunct to fibrinolysis in STEMI (see Table 10–8). In the only randomized clinical trial that compared two LMWHs head-to-head, enoxaparin was more efficacious than tinzaparin.[92]

A meta-analysis of four trials composed of 999 patients demonstrated a large reduction (5.5% to 2.6%, $P = 0.018$) in death or MI with the addition of UFH to aspirin compared with aspirin monotherapy (see Chapter 1).[1] Similarly, the FRISC trial[93] demonstrated a 63% reduction in death or MI at 7 days with the LMWH dalteparin plus aspirin compared with aspirin monotherapy (4.8% versus 1.8%, $P = 0.001$). The current practice guidelines support adding a heparin preparation (either UFH or LMWH) to aspirin in patients with probable or definite NSTE-ACS.[1]

Eight randomized trials have compared LMWH with UFH on a background of aspirin.[1] Dalteparin and fraxiparin did not improve outcomes compared with UFH in the FRIC[94] and FRAXIS[95] trials, respectively. In two double-blind trials from the late 1990s (ESSENCE[14] and TIMI 11B[91]), enoxaparin was associated with an approximate 20% reduction in the triple composite that was statistically significant in each study. Two additional large-scale open-label clinical trials (A to Z,[96] SYNERGY[97]), in which patients were more likely to be managed with an early catheterization, compared enoxaparin with UFH and concluded that enoxaparin is not inferior to UFH, thus confirming enoxaparin as an effective alternative.

Peterson and colleagues[98] provided a systematic evaluation of the outcomes in 21,946 patients in six randomized controlled clinical trials that compared enoxaparin with UFH in patients with NSTE-ACS (Fig.10–6). There was a 9% significant reduction in the composite of death or nonfatal MI after 30 days with enoxaparin and no differences in major bleeding or blood transfusions. Patients who received an antithrombin before randomization appeared to experience higher absolute rates of bleeding. Thus, the practice of switching between antithrombins in the same patient in the course of a single hospitalization should be avoided whenever possible.

Given similar or slightly better efficacy with enoxaparin compared with UFH in patients and other practical conveniences (twice daily subcutaneous injections, absence of the need for routine monitoring, and simple weight-based dosing), the use of enoxaparin generally should be preferred over UFH in most patients with NSTE-ACS (class IIa recommendation).[1] For patients at increased risk of bleeding or for whom an early invasive strategy is planned, the benefits of enoxaparin should be weighed against the trend toward an increased risk of bleeding that was observed in some studies that compared enoxaparin with UFH.

Direct Thrombin Inhibitors

There are three parenteral direct thrombin inhibitors (DTIs)—hirudin, bivalirudin, and argatroban—currently available for clinical use in the United States.[99-101] They are termed “direct” because they do not require a cofactor, as do the heparins, and they directly inhibit existing thrombin while having minimal effects on the proximal portions of the coagulation cascade (see Fig. 10–5). DTIs can broadly be classified as either monovalent (e.g., argatroban, inogatran) or divalent (e.g., hirudin, bivalirudin).

A meta-analysis of five trials involving 20,570 patients with NSTE-ACS randomized to a DTI versus UFH concluded that DTI reduced death or MI by 20% (OR 0.80, 95% CI 0.70 to 0.92) from 4.6% to 3.7% with similar effects on death (OR 0.82) and MI (OR 0.78) individually.[102] DTIs were associated with a near doubling in the rate of major bleeding (1.0%

Table 10–7 Dosing of Antithrombotic Agents in Patients with Non ST-Segment Acute Coronary Syndrome

Anticoagulant	Loading Dose	Maintenance Dose*
Bivalirudin	0.1-0.25 mg/kg IV	0.125-0.5 mg/kg IV for ≥ 72 h

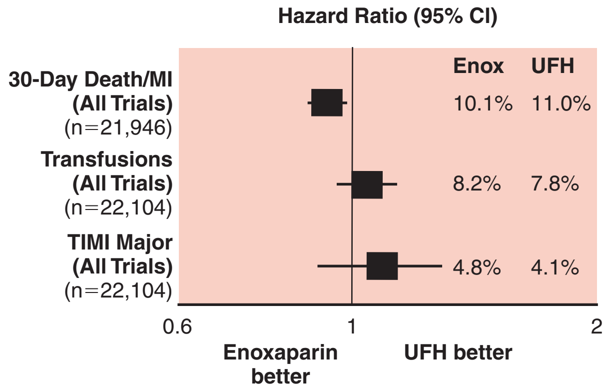
*Dependent on the specific direct thrombin inhibitor.



A to Z did not include CABG data.

Figure 10–6 In a systematic overview[98] of six randomized clinical trials comparing enoxaparin with unfractionated heparin (UFH) in 21,946 patients with non ST-segment elevation-acute coronary syndrome (NSTE-ACS), enoxaparin was associated with a statistically significant reduction (0.9% absolute) in the rate of death or new myocardial infarction at 30 days. Rates of major bleeding and transfusion tended to be slightly higher with enoxaparin. TIMI, Thrombolysis in Myocardial Infarction (With permission).

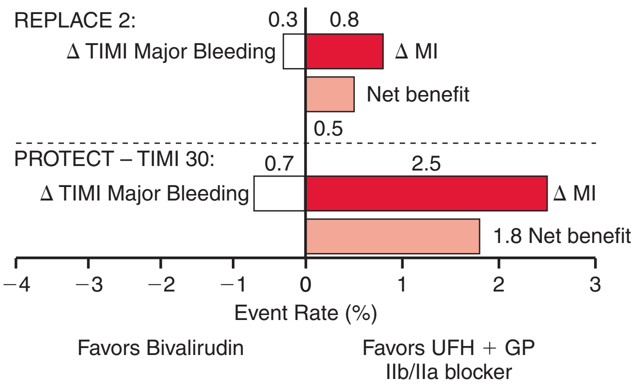


Figure 10–7 Comparison of bivalirudin (with provisional intravenous GP IIb/IIIa blocker) with unfractionated heparin (UFH) plus intravenous GP IIb/IIIa blocker with respect to the absolute difference in TIMI major bleeding, new myocardial infarction (MI) (mostly peri-PCI), and the net clinical benefit (difference in both endpoints combined) in REPLACE-2[80] and PROTECT-TIMI 30.[103] PCI, percutaneous coronary intervention; TIMI, Thrombolysis in Myocardial Infarction.

versus 0.5%; OR 1.79, 95% CI 1.29 to 2.50), however, heterogeneity in the applied definitions and observed results (both between different agents and across studies with the same agent) limits the precision of this estimate. In addition, the reductions in ischemic events were inconsistent across different DTIs, with no evidence of benefit with monovalent agents (inogatran, effegatran). Thus, in patients with a history of heparin-induced thrombocytopenia (HIT) or heparin-induced thrombocytopenia and thrombosis syndrome (HITTS), hirudin (and perhaps bivalirudin, although data are limited) is a reasonable alternative to LMWHs and UFH.

Data are becoming available on the use of DTIs in patients who are treated with more modern adjuncts including the thienopyridines, intravenous GP IIb/IIIa inhibitors, and drug-eluting stents. In the REPLACE-2 trial[80] of 6010 patients who were undergoing urgent or elective PCI, bivalirudin (with provisional use of an intravenous GP IIb/IIIa blocker in 7% of patients) was not inferior to the combination of UFH and an intravenous GP IIb/IIIa blocker, as assessed by the quadruple composite endpoint of death, MI, urgent target vessel revascularization, and major bleeding. No differences emerged in long-term efficacy (death, MI, or repeat revascularization). Among 857 moderate- and high-risk patients with ACS who were undergoing PCI in the PROTECT-TIMI 30 trial,[103] bivalirudin was associated with a lower rate of normal myocardial perfusion, a longer duration of ischemia on ambulatory ECG monitoring among patients with ischemia, a trend toward a higher composite rate of death, MI, or ischemia, but no difference in coronary flow reserve. In both studies, transfusions and serious bleeding rates were significantly reduced with bivalirudin. There were, however, numerically more periprocedural infarctions (Fig. 10–7). In sum, the available results indicate that bivalirudin may be a safer and equally or perhaps slightly less effective alternative to the combination of heparin with an intravenous GP IIb/IIIa blocker.

Preliminary results from the ACUITY trial, which compared bivalirudin with or without GP IIb/IIIa inhibition with heparin plus glycoprotein IIb/IIa inhibition in 13, 819 patients with acute coronary syndromes,[104] were presented at the 2006 ACC Scientific Sessions.[82,105] Treatment with bivalirudin alone was associated with a reduction in the net clinical benefit (death, reinfarction, unplanned revascularization for ischemia, major bleeding) compared with UFH/enoxaparin plus GP IIb/IIIa, although the results were primarily driven by a reduction in bleeding. Additionally, bivalirudin alone was non-inferior (25% boundary) to UFH/enoxaparin plus GP IIb/IIIa inhibitor for the triple ischemic endpoint (death, reinfarction, unplanned revascularization for ischemia). Detailed publication of the final results should help guide clinicians regarding the relative usefulness of these various therapeutic combinations. Current practice guidelines consider DTIs to be first line anticoagulants in NSTE-ACS patients with a history of heparin-induced thrombocytopenia (with or without thrombotic syndrome),[1] and as an alternative to UFH plus intravenous GP IIb/IIIa blockers in low-risk elective PCI patients who are at risk for bleeding.[106]

Oral DTIs have also been developed[107] and could potentially have a role during or after NSTE-ACS. In a dose-ranging trial post-MI, ximelagatran was more effective than placebo at reducing ischemic complications, although an excess in asymptomatic elevation of liver function tests was noted with ximelagatran.[108] Furthermore, in larger studies to prevent venothromboembolism and to prevent embolic stroke in atrial fibrillation, rare but serious clinical hepatotoxicity was observed,[109] and an FDA advisory panel has recommended against its approval.

Factor Xa Inhibitors

Several parenteral[110] and oral[111] pure inhibitors of Factor Xa have been developed, and one synthetic parenteral pentasaccharide (fondaparinux)[112] is approved for use in the prevention and treatment of venothromboembolism. The OASIS-5

trial[113] compared fondaparinux 2.5 mg administered once daily subcutaneously with enoxaparin (1 mg/kg SC every 12 hours) in 20,078 patients with NSTE-ACS. Fondaparinux was not inferior to enoxaparin with respect to the primary efficacy triple composite of death, MI, or recurrent ischemia through 9 days (5.8% vs. 5.7%, HR 1.01 [0.90 to 1.13]). Fondaparinux was associated with approximately one half the number of major bleeding events (2.2% vs. 4.1%, HR = 0.52, $P < 0.001$) and one quarter fewer transfusions, although the dosing of enoxaparin, particularly around the time of coronary angiography and PCI (when UFH was added in addition to enoxaparin), may not have been optimal. The mortality rates at 30 days ($P = 0.02$) and 6 months ($P = 0.05$) were lower with fondaparinux. Ongoing studies are evaluating long-acting pentasaccharides (idraparinux, administered SC once weekly) and oral factor Xa inhibitors.

Other Anticoagulants

Drugs with proximal targets in the coagulation cascade, such as tissue factor (TF) antibodies, TF pathway inhibitors, and TF/fVIIa complex inhibitors, are in the early stages of clinical development.[114] Drugs that modulate the mid-portion of the cascade (inhibitors of Factor IX and the protein C pathway) are also being developed. Drugs that target TF or the TF/FVIIa complex block the initiation of the coagulation cascade and appear to be potent inhibitors of new thrombin generation. In contrast, inhibitors of the mid-portion of the cascade prevent thrombogenesis by attenuating the propagation of coagulation. Because of the complexity and biologic redundancy of the coagulation system, it is difficult to predict from ex vivo mechanistic studies, which, if any, of these strategies will be most useful in clinical practice, although clinical studies are ongoing with several of these compounds.

INVASIVE VERSUS CONSERVATIVE STRATEGY FOR CARDIAC CATHETERIZATION

In addition to the pharmacologic measures used to treat patients with UA/NSTEMI, one of the most important decisions during hospitalization is the early strategy of care regarding coronary angiography and resultant revascularization. The goals of coronary angiography are to provide information about prognosis based on location and extent of coronary atherosclerosis and to identify patients who will derive clinical benefit from revascularization (either percutaneous or surgical). An *early conservative* strategy refers to medical management of patients, reserving the use of coronary angiography and revascularization for evidence of recurrent ischemia at rest (or with minimal activity) or a strongly positive predischarge stress test. An *early invasive* strategy refers to the routine recommendation for coronary angiography and revascularization (within 12 to 48 hours of presentation) in patients without contraindications.

Several clinical trials have been performed to evaluate the question of which strategy is superior in the treatment of patients with UA/NSTEMI. Early trials such as TIMI III B[115] and VANQWISH[116] showed similar clinical outcomes regardless of treatment strategy. However, more contemporary trials that employed modern antiplatelet, antithrombotic and catheterization techniques, including FRISC II[117] and TACTICS-TIMI 18,[118] have shown a significant benefit from pursuing an early invasive strategy, especially in patients who have indicators of high risk.

To reconcile the differences in clinical trials of invasive versus conservative strategies, three meta-analyses were performed. Each of the three meta-analyses[119-121] demonstrated a benefit for an early invasive strategy compared with an early conservative strategy. A meta-analysis by Mehta and colleagues that included TIMI 3B, VANQWISH, FRISC II, TACTICS and others[119] concluded that a routine invasive strategy was associated with a significant reduction in death or MI, a nonsignificant trend toward fewer deaths, and a significant relative reduction in MI alone through the end of follow-up, with an early increase in events outweighed by a later reduction (Fig. 10–8). A meta-regression analysis[120] showed that the most significant predictors of the benefits of an early invasive strategy were the use of aggressive antiplatelet treatment (defined as use of an intravenous GP IIb/IIIa blocker or thienopyridine in addition to aspirin) and intracoronary stenting in the early invasive group, a conclusion supported by a direct comparison of two trials performed before (TIMI IIIB) and after (TACTICS-TIMI 18) these agents were routinely available.[122] These combinatorial analyses have strengthened the evidence for a routine invasive strategy.

One study stands in contrast to the data that favor an early invasive strategy. In the ICTUS trial of 1200 patients with NSTE-ACS, an elevated troponin T, and either ischemic electrocardiographic changes or a documented history of CAD, randomization to an early invasive versus a selective invasive strategy demonstrated similar rates of death, MI, or rehospitalization for ACS at 1 year.[123] Potential explanations for the lack of benefit with an early invasive approach include the high rate of catheterization and revascularization in the conservative arm and a relatively short-term follow-up period compared with other studies.[124]

In summary, the majority of data suggest a benefit for patients with NSTE-ACS who are treated with an early invasive strategy. This benefit appears to be particularly strong in patients with high-risk indicators (Table 10–9), with the strongest benefit for those patients with ST-segment deviation and elevated cardiac troponins. In the absence of these findings, an equal recommendation is given for either strategy in clinical practice guidelines.[1] It should be noted, however, that patients treated conservatively should be managed invasively if they develop high-risk indicators or have a strongly positive stress test before discharge. Once an invasive strategy is undertaken, the decision for revascularization is based on the results of the coronary angiography and is similar to the indications for revascularization in patients with chronic stable angina,[125] with a stronger indication for some form of revascularization owing to the severity of presenting symptoms.

HOSPITAL DISCHARGE AND POST-HOSPITAL CARE

After the initial stabilization of an episode of NSTE-ACS with medical therapy and/or revascularization, patients remain at increased risk for major cardiovascular events for 1 to 3 months, and then they revert to a risk profile that approximates the

Study	Routine No./Total (%)	Selective No./Total (%)
Randomization to Hospital Discharge

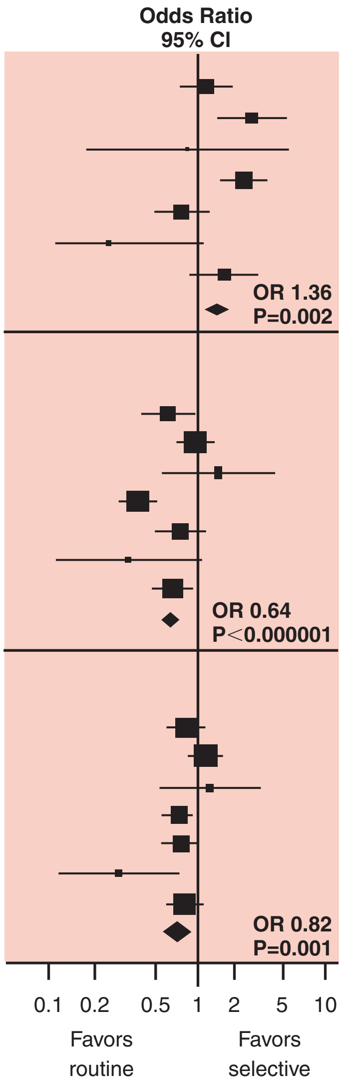

Figure 10–8 Composite of death or myocardial infarction (MI) in-hospital, post-discharge, and overall in trials of routine (early invasive) versus selective (early conservative) management of acute coronary syndrome (ACS).[119] Tests for heterogeneity: death or MI from randomization to hospital discharge, $P = 0.001$; death or MI after hospital discharge to follow-up, $P = 0.001$; death or MI from randomization to follow-up, $P = 0.06$. Random effects model results: death or MI from randomization to hospital discharge, relative risk (RR) 1.31, 95% CI 0.85 to 2.01; death or MI after hospital discharge to follow-up, RR 0.65, 95%CI 0.46 to 0.91; death or MI from randomization to follow-up, RR 0.82, 95%CI 0.68 to 0.99.

profile of patients with chronic stable CAD. Thus, institution of an effective comprehensive discharge plan is crucial to prevent early recurrent ischemic events. Critical pathways and various discharge tools are useful to increase adherence with treatment guidelines and have been associated with improved clinical outcomes.

Most patients can be discharged within 24 hours after a normal or low-risk noninvasive evaluation, or within 24 hours after uncomplicated PCI. Patients who are managed with CABG and have no major postoperative issues can generally be targeted for discharge to home or a short-stay rehabilitation facility on postoperative days 5 through 7. Three important goals in the discharge period include

1. Evaluation and patient education regarding NSTE-ACS, procedures performed, secondary risk factor reduction, and discharge medications, diet, and exercise.
2. Instructions regarding the appropriate level of activity and plans to resume usual activities in the near future.
3. Confirmation of long-term medical follow-up.

Table 10–9 High-Risk Indicators Favoring An Early Invasive Strategy for Patients with Unstable Angina/Non ST-Segment Elevation Myocardial Infarction[1]

- Recurrent angina/ischemia at rest or with low-level activities despite intensive anti-ischemic therapy
- Elevated cardiac troponin (I or T)
- New or presumably new ST-segment depression
- Recurrent angina/ischemia with CHF symptoms, an S3 gallop, pulmonary edema, worsening rales, or new or worsening mitral regurgitation
- High-risk findings on noninvasive stress testing
- Depressed left ventricular function (EF < 40%) on noninvasive testing
- Hemodynamic instability
- Sustained ventricular tachycardia
- Percutaneous coronary intervention (PCI) within 6 months
- Prior coronary artery bypass grafting (CABG)

CABG, coronary artery bypass graft; EF, ejection fraction; PCI, percutaneous coronary intervention.

A multidisciplinary approach that involves physicians and their assistants, nurses, pharmacists, dietitians, and rehabilitation specialists can help achieve these goals. Gluckman and associates[126] developed an "ABCDE" approach (Table 10–10) for the management of NSTE-ACS that provides a practical and systematic means to implement evidence-based medicine, including both medication (Table 10–11) and life-style modification (Table 10–12) into clinical practice.

Table 10–10 ABCDE Approach for the Management of Non ST-Segment Elevation Acute Coronary Syndrome

A: Antiplatelet therapy, **A**nticoagulation, **A**ngiotensin-converting enzyme inhibitor, **A**ngiotensin receptor blockade
Aspirin: ≥75 mg daily, continue indefinitely. Higher doses post-stenting.
Anticoagulation: atrial fibrillation, LV thrombus, severe wall-motion abnormalities
ACE-I: congestive heart failure, LVEF < 0.40, hypertension, diabetes. (May substitute ARB if intolerant of ACE-I).

B: β-blockade, **B**lood pressure control
β-blockade: all patients without absolute contraindications
Blood pressure control: goal < 130/85 mm Hg using lifestyle modifications and medications as needed.

C: Cholesterol treatment, **C**igarette smoking cessation
Cholesterol: Low saturated fat (<7% total calories), low cholesterol (<200 mg/day) diet rich in fish with omega-3 fatty acids (or supplemented by omega-3 supplements of 1 g/day). Goal LDL is <<100 mg/dL (optional target <70 mg/dL).
Cigarettes: ask, advise cessation, avoid second-hand exposure

D: Diabetes management, **D**iet
Diabetes: Goal glycosylated hemoglobin <7%, treat other risk factors
Diet: low in saturated fat and cholesterol, rich in omega-3 fatty fish, fresh vegetables, whole grains. Goal body mass index 18.5-24.9 kg/m^2. Routinely measure waist circumference, goal <40 inches (men), <35 inches (women).

E: Exercise: Ideally ≥30 minutes daily, supplemented by active lifestyle. Refer to cardiac rehabilitation/secondary prevention for patients with multiple risk factors or if supervised exercise program required due to high-risk status.

Available at: http://www.acc.org/clinical/guidelines/unstable/unstable/pdf.

Table 10–11 Discharge Medications for Patients with Non ST-Segment Elevation Acute Coronary Syndrome (NSTE-ACS)

Aspirin (75 to 325 mg daily)
Clopidogrel (75 mg daily for patients intolerant to aspirin), or in addition to aspirin for a period of up to 9 months
β-Blocker in the absence of absolute contraindications
Lipid-lowering agent and diet in patients with LDL > 130, or LDL > 100 after diet therapy
ACE inhibitor (or ARB if intolerant of ACE-I) for patients with CHF, LV dysfunction (EF < 40%), hypertension, or diabetes mellitus
Sublingual or spray nitroglycerin with instructions on proper use

Adapted from Braunwald E, Antman EM, Beasley JW, et al: ACC/AHA 2002 Guideline Update for the Management of Patients with Unstable Angina and Non ST-Segment Elevation Myocardial Infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on the Management of Patients with Unstable Angina). Available at: http://www.acc.org/clinical/guidelines/unstable/unstable/pdf.

Table 10–12 Lifestyle Modifications

Risk Factor	Goal/Target
Smoking cessation	Complete cessation, avoidance of secondary exposure
Weight control	BMI 18.5-24.9 kg/M^2 ; waist circumference <40 inches (men), <35 inches (women)
Exercise	Daily aerobic exercise for ≥30 minutes, minimum 3-4 times weekly*
Diet	≤7% calories from saturated fat, ≤200 mg/day cholesterol.
	↑ Fresh vegetables and fruit, fish rich in omega-3 fatty acids, whole grains, soluble fiber
Cholesterol management	LDL-C substantially <100 mg/dL, non-HDL substantially <130 mg/dL, TG < 200 mg/dL
Blood pressure control	<130/85 mm Hg (<130/80 if diabetes or chronic kidney disease), modest sodium restriction
Diabetes management	Glycosylated hemoglobin <7%
Depression/Anxiety	Assessment of psychosocial status, appropriate referral for support and/or therapy

*Optimally daily.

Available at: http://www.acc.org/clinical/guidelines/unstable/unstable/pdf.

Antiplatelet Therapy, Anticoagulation, Angiotensin-Converting Enzyme Inhibitor, Angiotensin Receptor Blockade

All patients without an absolute contraindication should be discharged on aspirin to be continued indefinitely.[1,42] Oral anticoagulation therapy at discharge is recommended for patients who have atrial fibrillation or left ventricular (LV) thrombus, and is reasonable in patients with LV dysfunction and extensive regional wall-motion abnormalities.[1,42,127] More frequent monitoring of the patient is advised when combining warfarin with antiplatelet therapy. ACE-I is indicated in patients with congestive heart failure, LV ejection fraction <0.40, hypertension, or diabetes.[1,42] For patients intolerant of ACE-I, an angiotensin receptor blocker may be substituted.

β-Blockade, Blood Pressure Control

β-Blockers are recommended for all patients in the absence of absolute contraindications[1,42] (see Anti-ischemic Medications, earlier). The dose should be adjusted as needed to manage angina and blood pressure, with a target blood pressure of <130/80 mm Hg.

Cholesterol Treatment, Cigarette Smoking Cessation

The primary goal of cholesterol management in patients after ACS should be a target LDL-C substantially less than 100 mg/dL (with an optional target of <70 mg/dL).[128] Statins, initiated *before* discharge, are preferred as first-line agents to lower LDL-C in patients with an LDL-C <100 mg/dL, whereas statins in combination with other lipid-lowering drugs (e.g., ezetimibe 10 mg/day, bile acid sequestrants, or niacin) may be necessary in patients whose LDL-C is >100 mg/dL. An additional key goal is to reduce the non-HDL-C (total cholesterol minus HDL cholesterol) to substantially <130 mg/dL.[129] If the triglycerides are 200 to 499 mg/dL after initiating LDL-C–lowering therapy, then a fibrate or niacin may be added. For patients with higher triglycerides levels, fibrate or niacin should be considered before initiating LDL-C–lowering therapy.

In the PROVE-IT-TIMI 22 trial,[130] 4162 patients hospitalized with ACS were randomized within 10 days to either pravastatin 40 mg or atorvastatin 80 mg daily and followed for a mean of 24 months. Atorvastatin 80 mg reduced the median LDL-C further (62 mg/dL versus 95 mg/dL, $P < 0.001$), and patients experienced 16% deaths or major cardiovascular events over 2 years ($P = 0.005$). Interestingly, the reduction in clinical events became apparent quite early (within 30 days) after the initiation of therapy.[131] An important corollary observed in PROVE-IT-TIMI 22 was that acute anti-inflammatory effects were associated with better clinical outcomes. In a retrospective analysis, patients who achieved a CRP level <2 mg/L had lower event rates than those who had higher CRP levels regardless of the LDL-C achieved (Fig. 10–9).[210] Prospective confirmation of the relationship between the achievement of the dual goals and improved clinical outcomes is underway in ongoing studies.

In the Z phase of the A to Z trial,[132] 4487 post-ACS patients were randomized to an early initiation of intensive statin (simvastatin 40 mg/day for 1 month followed by 80 mg/day thereafter) or a delayed conservative statin regimen consisting of diet with placebo for 4 months followed by 20 mg/day thereafter for an average of 2 years. A favorable trend toward a lower rate of the primary composite endpoint of cardiovascular death, nonfatal MI, readmission for ACS, and stroke was observed with the early intensive statin arm (14.4% versus 16.7% for the delayed conservative arm, $P = 0.14$). Although no difference between these arms was evident during the first 4 months after randomization, between 4 months through the end of the study, the primary composite was reduced significantly by 25% in the high-dose simvastatin group ($P = 0.02$).

The available data now support the use of an intensive statin regimen, such as atorvastatin 80 mg/day in patients post ACS, preferably commencing during the index admission. Reducing CRP appears to be an equally important goal. The IMPROVE IT trial is comparing the combination pill simvastatin/ezetimibe with simvastatin monotherapy in 10,000 patients stabilized within 10 days after admission for ACS.

The letter *C* (for cigarettes) in the *ABCDE* mnemonic also reminds the health care provider to ask the patient about his

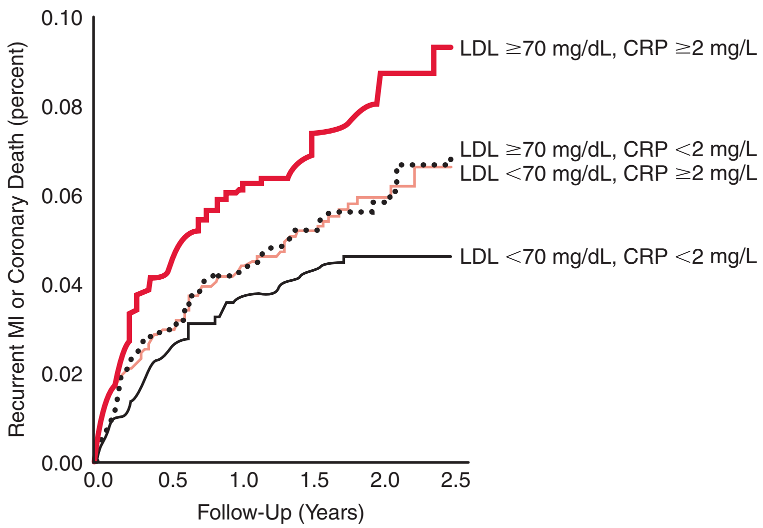

Figure 10–9 An analysis from the PROVE IT-TIMI 22 trial[210] of achieved LDL and achieved hs-CRP, stratified at cut points of 70 mg/dL and 2 mg/L, respectively, identified four groups of patients. Event rates were highest in the group with "high" LDL and "high" hs-CRP, and lowest in the group with "low" LDL and "low hs-CRP." PROVE IT-TIMI 22, Pravastatin or Atorvastatin Evaluation and Infectious Therapy—Thrombolysis in Myocardial Infarction 22; LDL, low-density lipoprotein; CRP, C-reactive protein. (With permission).

or her tobacco status. Patients and family members should be strongly encouraged to stop smoking, and avoidance of exposure to environmental tobacco smoke at work and home should be urged.[1] Practical measures that can be taken by all physicians include assessment of the patient's willingness to quit, counseling and developing a plan for quitting, considering pharmacologic therapy (e.g., nicotine replacement, buproprion), and referral to specialized programs.

Diabetes Management, Diet

The goal of diabetes management is a glycosylated hemoglobin <7%. A diet limiting saturated fats and dietary cholesterol, while rich in omega-3 fatty fish, vegetables, and whole grains, is recommended to achieve a goal body mass index of 18.5 to 24.9 kg/m^2 (weight in kg/height in meters squared).[1] The waist circumference should be measured as part of the evaluation, and increased values (>40 inches in men, >35 inches in women) should trigger lifestyle changes and consideration of treatment strategies for the metabolic syndrome.

Exercise

All patients ideally should exercise for a minimum of 30 minutes, preferably daily, but at a minimum of 3 to 4 days per week, supplemented by an increase in daily lifestyle activities such as walking during work breaks, gardening, and household work.[133] Referral to cardiac rehabilitation or secondary prevention programs is recommended for patients with multiple modifiable risk factors and for those patients at higher risk for whom a supervised exercise training program is indicated.

SPECIAL CONSIDERATIONS

Cardiac Syndrome X

The term "cardiac syndrome X," or more simply "syndrome X," was introduced in 1973 by Kemp in an editorial[134] commenting on a study that investigated ECG and hemodynamic responses to atrial pacing in patients with chest pain and normal coronary angiograms.[135] One interesting subgroup of patients, labeled group X, had normal LV performance function despite typical ischemic ECG changes and increased myocardial lactate production consistent with myocardial ischemia. The three characteristic features of this clinical entity include: (1) anginal discomfort with exertion, (2) ST-segment depression on exercise treadmill testing, and (3) normal coronary angiography (including no evidence of spontaneous or inducible spasm).[136,137] Although there is a lack of consensus regarding the specific definition of cardiac syndrome X (e.g., some definitions do not require the presence of ischemic ECG changes during exercise), and the pathogenic mechanisms responsible for this condition appear to be multiple, we include cardiac syndrome X in this chapter because up to 15% of patients with ACS do not have hemodynamically significant evidence of CAD by conventional angiography.[138] Importantly, cardiac syndrome X must not be confused with "metabolic syndrome X" (which is defined as patients who have at least three of the following five criteria: increased waist circumference, elevated triglycerides, high blood pressure, elevated fasting glucose, or depressed HDL)[139] although a small number of patients may have both conditions.

The two major pathogenic mechanisms that are believed to be responsible for cardiac syndrome X are coronary microvascular dysfunction[140] and abnormal cardiac pain sensitivity (either or both may be present in any one individual).[141] The presence of microvascular dysfunction is supported by studies that have demonstrated impairment of endothelial-dependent arterial vasodilatation—including coronary artery hyperreactivity and spasm in some patients; abnormal levels of metabolic/hormonal mediators of vascular tone (decreased nitric oxide production, estrogen deficiency, release of the endogenous peptides neuropeptide Y, endothelin-1); increased sensitivity to sympathetic stimulation with increased sympathetic tone; and prearteriolar constriction, and/or coronary vasoconstriction in response to exercise that may be due, in part, to increased platelet aggregability.[142,143] The observations that CRP levels are elevated in cardiac syndrome X[144] and that CRP has been related to endothelial dysfunction[145] are more evidence of the importance of coronary microvascular dysfunction as a potential mechanism.

Abnormal cardiac pain sensitivity is a nonischemic mechanism that also appears to be operative in a substantial proportion of patients with cardiac syndrome X. Studies have demonstrated enhanced pain perception,[146] exaggerated pain response to adenosine, abnormal release of interstitial potassium, and activation of the right anterior insula cortex that may result in abnormal neural function.[147] It has also been postulated that both microvascular dysfunction and abnormal pain perception are operative as independent abnormalities, and that in some patients, the cardiac syndrome X becomes manifest only because of the presence of coronary microvascular dysfunction in patients with increased cardiac pain perception.[143]

Reassurance regarding the overall excellent prognosis remains the first step in management of patients with cardiac syndrome X. Treatments to prevent angina generally fall into one of four major categories: anti-ischemics, agents that improve endothelial function, analgesics, and lifestyle/behavioral approaches.[148] The most extensive data support the use of β-blockers as first-line therapy, with studies demonstrating a reduction in chest pain, less exercise-induced ST-segment depression, fewer episodes of silent ischemia by Holter monitoring, improvement in microcirculation, and better quality of life. Data from clinical trials have also (inconsistently) supported a role for nitrates and calcium channel blockers, particularly to reduce exercise-induced angina and ischemic ST changes. Nicorandil[149] (an adenosine triphosphate sensitive potassium channel opener that also has nitrate-like effects) and trimetazidine[150] (an inhibitor of oxidative phosphorylation that shifts energy production from free fatty acid to glucose oxidation) have also been associated with improvements in exercise tolerance, whereas α-blockers and aminophylline appear to have a more limited role in selected patients.

Because impairment in normal endothelial function of the coronary microvasculature that results in inadequate flow reserve appears to play an important role in some patients with cardiac syndrome X, therapies aiming to improve endothelial function have been tried with modest success. In a placebo-controlled trial, pravastatin 40 mg/day improved brachial artery flow-mediated dilatation, exercise duration, and time to ischemia in patients with cardiac syndrome X.[151] A study combining ACE-inhibition with statin therapy sug-

gested that these agents can improve endothelial function and quality of life in cardiac syndrome X and may work by reducing oxidative stress (as determined by superoxide dismutase activity) in the vascular wall.[152] Estrogen therapy, while improving endothelium-dependent coronary vasomotion in some postmenopausal women with cardiac syndrome X, is controversial, particularly in light of randomized trials of hormonal replacement that demonstrate an increase risk of cardiovascular events.[153]

When anti-ischemic drugs and statins prove ineffective at controlling symptoms, a trial of analgesic-based therapies is recommended, given the evidence of altered somatic and visceral pain perception in some patients with cardiac syndrome X. Imipramine reduced chest pain in placebo-controlled trials, including studies with[154] and without[155] concomitant background anti-ischemic therapy. Monitoring of side effects (e.g., dizziness, dry mouth, constipation) is necessary because these can have an adverse impact on quality of life.[154] Electrostimulation techniques such as transcutaneous electrical nerve stimulation[156] and spinal cord stimulation[157] reduced symptoms in studies of patients with angina and normal coronary angiograms, and thus may be considered for patients with angina refractory to multiple drug therapies. Physical training improves exercise capacity and delays the onset of exercise-induced angina, particularly among patients who are deconditioned.[158] Structured cognitive behavioral approaches, particularly if instituted early after diagnosis, may be helpful to reduce chest pain and the psychological morbidity associated with cardiac syndrome X.[159-162]

Because there is heterogeneity among patients diagnosed with cardiac syndrome X, an individualized patient-based approach that attempts to achieve optimal symptom control, using multiple disciplines if necessary, is recommended. Reassurance regarding the excellent intermediate-term prognosis along with a sympathetic appreciation by the physician of the adverse impact on quality of life that patients often experience are keys to success. A stepwise and largely empiric approach is described in Figure 10–10, pending additional data from randomized studies.

Cocaine Use and Acute Coronary Syndromes

Cocaine use results in a marked increase in sympathetic tone by blocking the reuptake of norepinephrine from synapses by preganglionic neurons. The use of cocaine favors myocardial ischemia and infarction through several mechanisms including increases in myocardial oxygen demand, decreases in myocardial oxygen supply, and accelerated atherosclerosis and thrombosis.[163] Oxygen demand is increased by increases in heart rate, myocardial contractility, and wall stress (β-adrenergic effects); supply is limited by vasoconstriction (α-adrenergic effects). However, the cardiovascular toxicity is not limited to dynamic effects. Cocaine also produces endothelial damage, enhanced platelet activation and aggregation, and decreases in plasminogen activator inhibitor.[163] Although the risk of events is highest when concentrations of cocaine in the blood are maximal and heart rate and blood pressure effects are apparent, these alternate pathophysiologic mechanisms may help to explain why patients using cocaine continue to be at risk for increased cardiac ischemic events after cocaine levels have decreased.

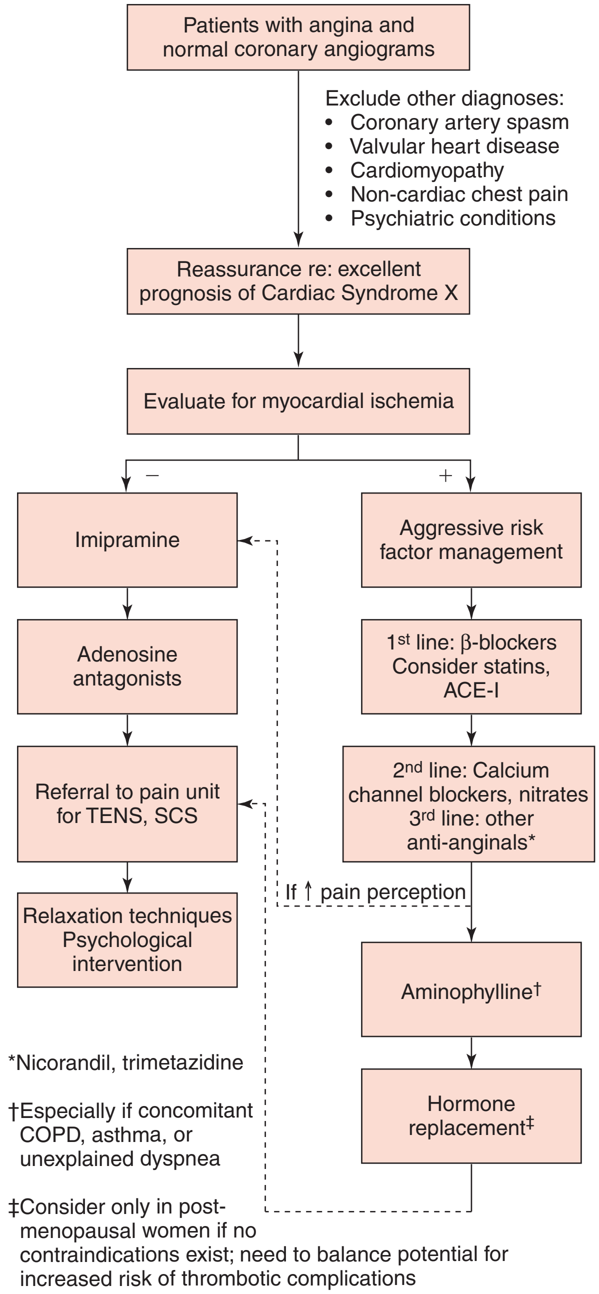

Figure 10–10 A stepwise approach to the diagnosis and management of patients with syndrome X.

The common use of cocaine among patients who present to emergency departments with chest pain and the differences in treatment between cocaine-induced coronary ischemia and patients without cocaine use mandate that the health care provider be vigilant to the possibility of use among all patients. Use of selective β-adrenergic receptor blockers can exacerbate coronary vasoconstriction in users of cocaine by creating a relative excess of β-adrenergic stimulation. Therefore, the use of selective β-blockers (as opposed to mixed α- and-β-blockers) as first-line agents for cocaine-related myocardial ischemia is discouraged.[163] Cocaine-related vasospasm can be reversed by verapamil, nitroglycerin, and α-adrenergic blockers such as phentolamine. Nitrates and calcium channel blockers and benzodiazepines are generally

considered first-line treatment for cocaine-related ischemia.[1] The clinician should remember, however, that coronary thrombosis is not infrequent with cocaine use, and aspirin and other antithrombotic measures should be taken. In the presence of refractory ischemia, cardiac catheterization with percutaneous intervention may be necessary.[1]

Women

Although CHD has traditionally been considered a disease of middle-aged men, approximately 43% of patients discharged with ACS from U.S. hospitals in 2003 were female.[5] In general, women diagnosed with NSTE-ACS should be managed in a manner similar to men, despite an under-representation of women in published trial literature that serves as the primary evidence for treatment guidelines. A number of key observations that pertain to women (on average) should be kept in mind. Women with NSTE-ACS tend to be older than men, with an incidence of CHD that lags by approximately one decade until the seventh decade.[164] The "typical" presentation of ACS that is based on earlier studies predominantly in men, differs from the "typical" presentation in women that is more complex and multifactorial.[165] Nonatherosclerotic etiologies of angina (e.g., microvascular dysfunction[166]) are more frequent in women than in men. Differences in the distribution and synergy of traditional and novel risk factors (e.g., CRP,[167] anemia[168]) between the sexes may explain the unique high-risk profile of certain subgroups of women with a protracted dysmetabolic state,[169] such as prematurely menopausal women who also have diabetes[170] or who smoke.[171] Gender-specific differences in pathophysiologic processes, possibly mediated by reproductive hormones (e.g., estrogen deficiency) may be responsible for the observed differences in biomarker profiles (lower troponin, higher BNP).[172]

Evaluation of women with biomarkers, ECG, noninvasive testing, and coronary angiography should be similar to an evaluation in men, although a few points deserve to be highlighted. Repolarization abnormalities on resting ECG are strong independent predictors of CHD events, mortality, and CHF in postmenopausal women.[173,174] Exercise ECG testing is less specific in women, and addition of an imaging study to the stress ECG improves diagnostic accuracy.[175,176] Because women have a more complex, multifactorial etiology of NSTE-ACS and greater diagnostic uncertainty, assessment of additional information (such as evaluation of plaque burden, vascular reactivity,[177] and functional capacity[178]) may be of relatively greater importance in women.[165] Similar to men, women with a high-risk indicator or with high-risk noninvasive test results should be referred for coronary angiogram with the understanding that women are at higher risk for bleeding complications, in part due to older age, lower body weight, and impaired renal function.

The reasons that women tend to be treated less intensively than men are likely complex and multifactorial.[179] Nonetheless, the underuse of proven therapies in NSTE-ACS that have a high benefit:risk ratio (e.g., aspirin, statin) indicates the presence of a gender treatment bias[180] that persists despite publication of numerous treatment guidelines over the past decade.[181] Women with CAD are referred less frequently for coronary angiography and revascularization,[181] in part due to the presence of less extensive epicardial CAD. The observation that women continue to have modestly poorer adjusted outcomes (particularly in the incidence of recurrent angina and CHF)[182] after revascularization, despite less extensive epicardial disease, suggests that we lack an adequate understanding of the relations between the gender differences in symptoms, risk factors, and pathophysiology.[183] Targeting obesity and physical inactivity may be especially important after NSTE-ACS as these factors contribute independently to CHD morbidity and mortality rates in women.[184]

Diabetes Mellitus

The prevalence of diabetes increased by 61% in the United States from 1990 to 2000, with some states experiencing rates of diagnosed diabetes in excess of 10%.[5] Because heart disease death rates among adults with diabetes are two- to fourfold higher than in adults without diabetes, and because nearly two thirds of all diabetics die of some form of heart or blood vessel disease,[185] diabetic patients with NSTE-ACS deserve particular attention.

In the Global Registry of Acute Coronary Events, more than one fourth of patients with NSTE-ACS had diabetes.[186] Diabetics tend to have a greater number of comorbidities, such as advanced age, prior CAD, history of heart failure, hypertension, and obesity—although they are less likely to smoke. Nevertheless, after multivariate adjustment, diabetes itself confers a 20% to 30% increased risk of death or ischemic complications.[187]

Established medical therapies for NSTE-ACS should be administered to diabetics as they are to nondiabetics, with additional attention directed toward tight control of blood glucose. Diabetics have a worse long-term outcome after revascularization compared with nondiabetics, in particular after PCI,[188] because they are at a higher risk for restenosis and disease progression of nonculprit lesions. Use of GP IIb/IIIa inhibitors and intracoronary stents appears to be of particular benefit in diabetics who undergo PCI.[189] With use of the left internal mammary artery as a bypass conduit, CABG is preferred over PCI in diabetics with multivessel disease,[190] although additional studies are needed with newer therapies (e.g., drug-eluting stents, thienopyridines) to determine the optimal role for multivessel PCI in diabetics.

The Elderly

Prevalent coronary artery disease increases with aging. As a result, elderly patients are over-represented among patients with coronary disease. It is reported that 20% of the hospitalizations for MI and, because adverse outcomes are more prevalent in the elderly, 30% of MI deaths are seen in the 5% of the U.S. population in their 80s.[191] Despite the burden of risk in elderly patients, evidence-based therapies are underused in this age group.[192-194]

More frequent medical and cardiac comorbidities affect all aspects of the diagnosis and management of elderly patients with NSTE-ACS. Risk factors and physiologic differences also are manifest in the care of older patients with NSTE-ACS. In the TIMI III registry, elderly patients were more likely to have systemic hypertension and a history of myocardial infarction, but less likely to have hypercholesterolemia, family history of coronary artery disease, or to smoke than the non-elderly.[194] Elderly patients are more likely than younger patients to have noncoronary causes of NSTE-ACS: hyperten-

sion, myocardial hypertrophy, and diastolic dysfunctions.[195] In addition, reduced hepatic and renal function results in impaired metabolism and clearance of medication. Elderly patients tend to have decreased arterial compliance that results in increased cardiac afterload and diminished β-sympathetic response.[196] These factors, combined with polypharmacy, increase the risk of drug–drug interactions and side effects in the elderly.

Elderly patients are more likely to present with atypical symptoms of UA/NSTEMI such as shortness of breath or congestive heart failure resulting from exaggerated increases in ventricular pressures.[197] Therefore, a high index of suspicion must be maintained for diagnosis of UA/NSTEMI in the elderly.

General recommendations for the pharmacologic treatment of UA/NSTEMI in the elderly is to follow the accepted treatment for younger patients, recognizing and anticipating increased side effect profiles of therapeutics in this population.[198] However, greater caution regarding dosing and monitoring of side effects is necessary. For instance, older patients are more prone to exaggerated hypotensive effects of nitroglycerin.[199] Elderly patients have diminished responsiveness to adrenergic stimuli and decreased atrioventricular (AV) nodal conduction, thus the response to β-blockers may not be predictable. Of particular importance, the prevalence of reduced renal function in the elderly is high, even in the setting of seemingly normal serum creatinine. Specific calculation of creatinine clearance or glomerular filtration rate should be performed in the elderly to guide therapy and dose medications that are cleared by the kidney.

Decisions regarding invasive or conservative management must also be considered in the context of the age of the patient. Elderly patients are more likely to have severe coronary artery disease which could benefit from invasive management, but also are more likely to have medical comorbidities that can result in adverse outcomes. Observational studies have shown that elderly patients are much less likely than younger patients to undergo coronary angiography and revascularization.[194,200] Studies have shown results similar to younger patients in carefully chosen subjects[201]; however, some studies show decreased procedural success rates and increased complications at extremes of age[202,203] including an increase in periprocedural MI.[204]

Most clinical trials have not specifically addressed the issue of invasive versus conservative management of the elderly. One prospective randomized trial (the TIME trial) of invasive versus conservative therapy in patients older than 75 years with *chronic* coronary artery disease has been published.[205] Patients who were undergoing revascularization had a lower rate of major adverse cardiac events at 6 months and improvement in symptomatic status compared with patients with an initial conservative management strategy. In an analysis of the TACTICS-TIMI 18 trial,[206] a larger clinical benefit was seen in elderly patients who were undergoing an invasive strategy than in younger patients, but was somewhat offset by an increased rate of hemorrhage in elderly patients. A similar pattern of risk and benefit was observed in the FRISC II trial, with the majority of the benefit of early invasive therapy being seen in patients older than 65 years.[117]

As with other treatments, the rates of important adverse events, including cerebrovascular events, after CABG is significantly increased in elderly patients.[207] Observational studies showed, however, improved clinical outcomes among octogenarians who underwent CABG compared with patients with similarly severe CAD who did not undergo CABG.[208]

An approach to the care of an elderly patient with NSTE-ACS should focus on factors similar to the management of younger patients. Because of physiologic and psychosocial differences, and because of more frequent polypharmacy and medical comorbidities, each therapy should be considered specifically for its possible adverse effects and interactions. The practitioner should attempt to identify the signs and symptoms of depression in the elderly and provide treatment.[191] Additionally, the importance of physical therapy and rehabilitation to maintain mobility and enhance recovery is magnified in the elderly.[191] **In summary, data suggest that well chosen elderly patients are likely to derive an important benefit from proven strategies. Barring medical comorbidities that provide contraindications, advanced age should be considered an indication for comprehensive treatment of NSTE-ACS, not a contraindication to it.**

ST-Elevation Myocardial Infarction

Eric R. Bates and Frederick G. Kushner

CHAPTER CONTENTS

ST-elevation myocardial infarction (STEMI) is a significant health problem in industrialized countries and is becoming an increasingly significant problem in developing countries.[1] There are approximately 500,000 STEMI events in the United States each year.[2] One third of patients will die within the first 24 hours of presentation, many with sudden death.[1] In the last few decades, there has been a steady decline in the mortality rate from STEMI, but the rate of decline appears to have slowed. This appears to be due to both a fall in the incidence of STEMI and a reduction in the case fatality rate.[3] There has been a progressive increase in the proportion of patients who present with non-ST segment elevation myocardial infarction compared with STEMI. This chapter will follow the clinical course of the STEMI patient from before STEMI to management in the prehospital setting, the Emergency Department, the hospital, and after hospital discharge.[2]

PRE-STEMI MANAGEMENT

Primary and secondary prevention interventions aimed at the risk factors associated with coronary heart disease (CHD) reduce the risk of STEMI.[4,5] These include smoking cessation,[6] diet, exercise, lipid management,[7] blood pressure control,[8] and diabetes management (see Chapter 9). Primary care providers should evaluate the presence and status of control of major risk factors for CHD for all patients every 3 to 5 years. The 10-year risk of developing symptomatic CHD should be calculated for all patients who have two or more major risk factors to assess the need for primary prevention strategies.[4,7,9] Patients with established CHD should be identified for secondary prevention, and patients with a CHD risk equivalent (e.g., diabetes mellitus, chronic kidney disease, peripheral vascular disease, or a 10-year risk >20% as calculated by the Framingham equations) should receive equally intensive risk factor intervention as those with clinically apparent CHD.[10]

Morbidity and mortality due to STEMI can be reduced if patients and bystanders are taught to recognize symptoms early and activate the Emergency Medical Services (EMS) system.[11] Patients with symptoms of STEMI should be transported to the hospital by ambulance, instead of by automobile, so that they can receive cardiopulmonary resuscitation (CPR) and defibrillation, if necessary, and they should receive early reperfusion therapy at the nearest appropriate hospital.

Although the traditional recommendation is for patients to take one sublingual nitroglycerin dose 5 minutes apart for up to three doses before calling EMS, this recommendation has been modified to encourage earlier contact by STEMI patients.[12] If symptoms suggestive of STEMI are unimproved or worsening 5 minutes after one nitroglycerin tablet, patients should immediately call 911 to access EMS.

PREHOSPITAL MANAGEMENT

Symptom Recognition

Early recognition of symptoms of STEMI is the first step in the "Chain of Survival."[13] Although most patients recognize chest pain as a symptom of STEMI, many are unaware of associated symptoms, such as arm pain, lower jaw pain, shortness of breath, and diaphoresis or anginal equivalents.[14] For a variety of reasons the average patient does not seek medical attention for at least 2 hours after symptom onset.[15] Longer delay times occur among non-Hispanic blacks, older patients, Medicaid patients, and women.[16,17] Fully one third of patients with confirmed STEMI may present to the hospital with symptoms other than chest discomfort[18] and as many as one half of all STEMI events are clinically silent or unrecognized by the patient.[19] A high index of suspicion for STEMI should be maintained when evaluating women, diabetics, older patients, and those with a history of heart failure, as well as those patients complaining of chest discomfort but who have a permanent pacemaker or bundle branch block that may confound the recognition of STEMI on their electrocardiogram (ECG).

Out-of-Hospital Arrest

The majority of deaths from STEMI occur in the first 1 to 2 hours after symptom onset, usually from ventricular fibrillation (VF). Every minute in VF decreases the chance of survival by 7% to 10%.[13] Key elements of the "Chain of Survival" include early activation of the EMS system, early CPR and defibrillation for those who need it, and advanced cardiac life support (ACLS).[13,20] Family members of STEMI patients should be advised to take CPR and automated external defibrillator (AED) training.

Emergency Medical Services Systems

To minimize time to treatment, particularly for cardiopulmonary arrest, many communities allow volunteers and/or paid firefighters and other first-aid providers to function as first responders, providing CPR and early defibrillation using an AED until emergency medical technicians (EMTs) and paramedics arrive. The EMS ambulance response is a tiered system. The basic EMT level includes first aid and early defibrillation with AEDs. Other units are staffed by paramedics or other intermediate level EMTs who can give basic care, start IVs, intubate, and administer medications. In some systems, the advanced providers can also perform a 12-lead ECG, provide external pacing for symptomatic bradycardia, and employ other techniques.[21] Some high performance EMS systems have only advanced life support-staffed ambulances.

Prehospital EMS providers should administer 162 to 325 mg of chewable aspirin, unless contraindicated, to patients suspected to be experiencing STEMI. The use of 12-lead ECGs by paramedics to evaluate all patients with possible ischemic chest discomfort in the prehospital setting is strongly encouraged. For patients with ECG evidence for STEMI, a reperfusion checklist may be relayed along with the ECG to a predetermined medical control facility or hospital.

Prehospital Fibrinolysis

Randomized controlled trials have demonstrated the benefit of initiating fibrinolytic therapy as early as possible after the onset of STEMI.[22,23] Prehospital administration allows one half of patients to be treated within 2 hours of symptom onset when the greatest treatment benefit can be expected.[24] A French national registry demonstrated lower 1-year mortality with prehospital fibrinolytic therapy than with in-hospital fibrinolysis or primary PCI[25] (Fig. 11–1). However, a prehospital fibrinolytic program requires either a physician in the ambulance or a highly organized program with well-trained paramedics that can transmit the ECG to a medical command center with a medical director.

Prehospital Destination Protocols

Every community should have a written protocol that guides EMS system personnel in determining where to take patients with suspected or confirmed STEMI (Fig. 11–2). In general, patients with suspected STEMI should be taken to the nearest appropriate hospital. However, patients with contraindications to lytic therapy or patients with severe heart failure or cardiogenic shock should be transported directly or secondarily transported to a hospital with revascularization capability so that they can receive revascularization therapy. Hospitals without revascularization capability should also have an interhospital transfer protocol in place for patients who fail fibrinolytic therapy and are candidates for rescue PCI.

EMERGENCY DEPARTMENT MANAGEMENT

Patient Triage

The effectiveness of a variety of treatment options diminishes rapidly within the first several hours following symptom onset, so rapid triage is important.[26,27] The traditional Emergency Department (ED) evaluation of patients with chest pain relies heavily on the patient's history, physical examination, and ECG. All patients presenting to the ED with chest discomfort or other symptoms suggestive of STEMI should be placed on a cardiac monitor immediately with emergency resuscitation equipment nearby, including a defibrillator. An intravenous line should be started for rapid delivery of medications. An ECG should be performed and shown to an experienced Emergency Medicine physician within 10 minutes of ED arrival. Advanced directives should be clarified, especially in elderly patients, to prevent treatment contrary to the patient's wishes. If STEMI is present, the decision as to whether the patient will be treated with fibrinolytic therapy or primary PCI should be made within the next 10 minutes. The goal should be to achieve a door-to-needle time within 30 minutes or a door-to-balloon time within 90 minutes. If the initial

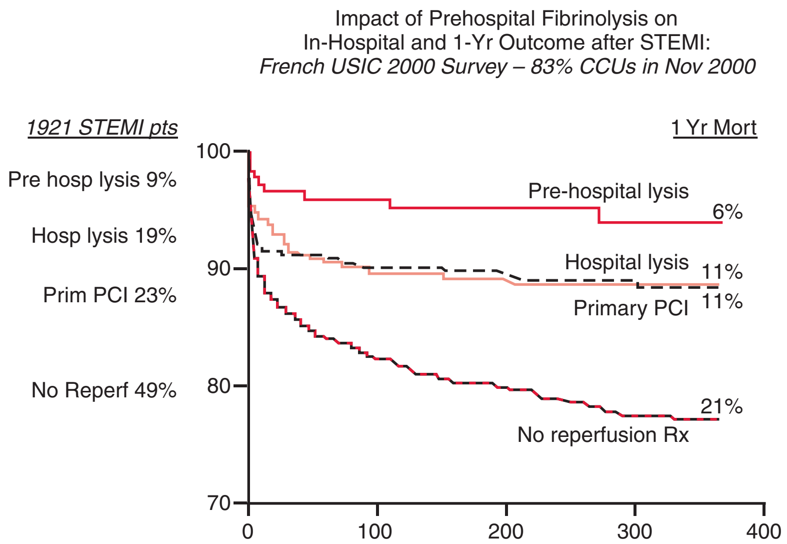

Figure 11–1 Age-adjusted Kaplan-Meier 1-year survival according to reperfusion strategy in the French USIC 2000 survey of 83% of coronary care units in November 2000. After adjustment by Cox multivariable analysis, prehospital thrombolysis remained associated with improved survival. CCUs, coronary care units; PCI, percutaneous coronary intervention; STEMI, ST-elevation myocardial infarction. (Reproduced from Danchin N, Blanchard D, Steg PG, et al: Impact of prehospital thrombolysis for acute myocardial infarction on 1-year outcome: Results from the French Nationwide USIC 2000 Registry. Circulation 2004;110:1909-15).

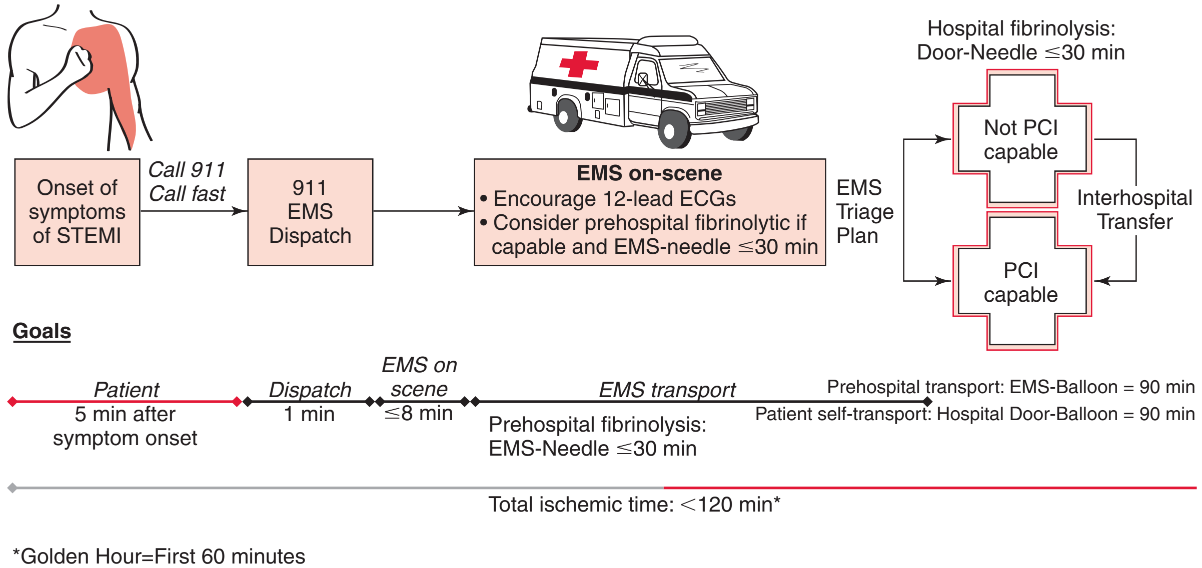

Figure 11–2 Options for transportation of patients with STEMI and initial reperfusion treatment. Patient transported by EMS after calling 911: Reperfusion in patients with STEMI can be accomplished by the pharmacologic (fibrinolysis) or catheter-based (primary PCI) approaches. Implementation of these strategies varies based on the mode of transportation of the patient and capabilities at the receiving hospital. Transport time to the hospital is variable from case to case, but the goal is to keep total ischemic time within 120 minutes. There are three possibilities (1) if EMS has fibrinolytic capability and the patient qualifies for therapy, prehospital fibrinolysis should be started within 30 minutes of EMS arrival on scene; (2) if EMS is not capable of administering prehospital fibrinolysis and the patient is transported to a non–PCI-capable hospital, the hospital door-to-needle time should be within 30 minutes for patients in whom fibrinolysis is indicated; (3) If EMS is not capable of administering prehospital fibrinolysis and the patient is transported to a PCI-capable hospital, the hospital door-to-balloon time should be within 90 minutes. Interhospital transfer: It is also appropriate to consider emergency interhospital transfer of the patient to a PCI-capable hospital for mechanical revascularization if (1) there is a contraindication to fibrinolysis; (2) PCI can be initiated promptly (within 90 minutes after the patient presented to the initial receiving hospital or within 60 minutes compared with when fibrinolysis with a fibrin-specific agent could be initiated at the initial receiving hospital; (3) fibrinolysis is administered and is unsuccessful (i.e., "rescue PCI"). Secondary non-emergency interhospital transfer can be considered for recurrent ischemia. Patient self-transport: Patient self-transportation is discouraged. If the patient arrives at a non–PCI-capable hospital, the door-to-needle time should be within 30 minutes. If the patient arrives at a PCI-capable hospital, the door-to-balloon time should be within 90 minutes. The treatment options and time recommended after first hospital arrival are the same. (Adapted from Armstrong PW, Collen D, Antman E: Fibrinolysis for acute myocardial infarction: The future is here and now. Circulation 2003;107:2533-7, with permission.)

ECG is not diagnostic, the patient remains symptomatic, and there is a high clinical suspicion for STEMI, serial ECGs at 5- to 10-minute intervals or continuous ST-segment monitoring should be performed. The choice of initial STEMI treatment should be made by the Emergency Medicine physician on duty in the ED based on a predetermined, institution-specific, written protocol. If the initial diagnosis and treatment plan are not clear, immediate cardiology consultation should be obtained.

Patient Evaluation

A targeted history should ascertain whether the patient has had prior stable or unstable angina, myocardial infarction (MI), coronary artery bypass graft (CABG) surgery, or PCI. Evaluation of the patient's complaints should focus on chest discomfort, associated symptoms, gender- and age-related differences in presentation, hypertension, diabetes mellitus, possibility of aortic dissection, risk of bleeding, and clinical cerebrovascular disease (amaurosis fugax, face/limb weakness or clumsiness, sensory loss, ataxia, or vertigo). A brief targeted physical examination should focus on potential complications of STEMI. A differential diagnosis should be reviewed to exclude other conditions that may mimic STEMI.

The 12-lead ECG in the ED is at the center of the therapeutic decision pathway. The risk of mortality increases with the number of ECG leads that show ST-segment elevation and with the sum of ST-segment deviation in 12 leads.[28] Important predictors of mortality include anterior location and left bundle branch block (LBBB). Patients with ≥0.1 mV ST-elevation in two contiguous leads are candidates for reperfusion therapy. Patients with inferior STEMI should have right-sided leads obtained to screen for ST-elevation suggestive of right ventricular (RV) infarction. Although patients without ST-elevation should not be treated with fibrinolytic therapy, its use is appropriate when there is marked ST-segment depression confined to leads V1 through V4 and accompanied by tall R waves in the right precordial leads and upright T waves indicative of a true posterior injury current.[29] Patients with new or presumed new LBBB and signs and symptoms of STEMI should also be considered for reperfusion therapy.

Laboratory examinations should include serial cardiac biomarkers (CK-MB, troponins) for cardiac damage, CBC, platelet count, INR, aPTT, electrolytes, magnesium, BUN, creatinine, glucose, and serum lipids. Therapeutic decisions should not be delayed until these results are returned. Cardiac biomarkers are useful for confirming the diagnosis of STEMI, assessing the success of fibrinolytic therapy, estimating infarct size, and providing prognostic information.

Several imaging tests can be used to evaluate patients with chest pain. A portable chest radiograph should be obtained, but should not delay initiation of reperfusion therapy. Transthoracic and/or transesophageal echocardiography is useful for evaluating ventricular function and diagnosing mechanical complications. A contrast chest CT may be required to exclude aortic dissection. CT angiography and magnetic resonance imaging are investigational techniques. Radionuclide imaging is not indicated in the acute setting.

Routine Measures

Oxygen

Supplemental oxygen should be administered by nasal prongs for at least 6 hours because of possible ventilation-perfusion mismatch or excessive lung water.[30] It should be discontinued after 6 hours if the arterial saturation is >90%. In patients with severe CHF, pulmonary edema, or mechanical complications, endotracheal intubation and mechanical ventilation may be required.

Nitroglycerin

Nitrates are indicated to relieve ischemic pain, control hypertension, and as a vasodilator in patients with LV failure or coronary spasm. Clinical trial results have suggested only a modest benefit from nitroglycerin therapy. A pooled analysis of more than 60,000 patients treated with nitrate-like preparations intravenously or orally in 22 trials revealed a mortality rate of 7.7% in the control group, that was reduced to 7.4% in the nitrate group. These data are consistent with a possible small treatment effect of nitrates on mortality rates (3 to 4 fewer deaths for every 1000 patients treated).[31]

Nitrates should be avoided in patients with initial systolic blood pressures <90 mm Hg, marked bradycardia or tachycardia, and in patients with known or suspected right ventricular infarction.[32] Phosphodiesterase inhibitors potentiate the hypotensive effects of nitrates by releasing nitric oxide.[33] Therefore, nitrates should not be administered to patients who have used a phosphodiesterase inhibitor for erectile dysfunction in the preceding 24 to 48 hours.

Patients with ongoing ischemic discomfort should receive sublingual nitroglycerin (0.4 mg) every 5 minutes for a total of 3 doses, after which an assessment should be made about the need for intravenous administration. A useful intravenous regimen employs an initial infusion rate of 5 to 10 mcg per minute with increases of 5 to 20 mcg per minute until symptoms are relieved or mean arterial blood pressure is reduced by 10% of its baseline level in normotensive patients and by up to 30% in hypertensive patients. In no case should the systolic pressure be brought below 90 mm Hg or drop 30 mm Hg below baseline. In view of their marginal treatment benefits, nitrates should not be used if hypotension limits the administration of β-blockers or ACE inhibitors, which have more powerful salutary effects.

Analgesia

The clinician should focus on two aspects of pain management (1) acute relief of the symptoms of ongoing myocardial ischemia and necrosis; and (2) the general relief of anxiety and apprehension that frequently exacerbate pain. Pain, which is commonly severe in the acute phase of STEMI, contributes to the hyperadrenergic state that has been implicated as having a role in plaque fissuring and thrombus propagation, and in reducing the threshold for ventricular fibrillation.

The tendency to underdose patients should be avoided. Control of cardiac pain is typically accomplished with a combination of nitrates, opiate analgesic agents, oxygen, and β-blockers. Morphine sulfate has remained the analgesic agent of choice for STEMI patients. The dose required varies in relation to age and body size as well as to blood pressure and heart rate. Morphine sulfate (2 to 4 mg intravenously with increments of 2 to 8 mg intravenously, repeated at 5 to 15 minute intervals) may be given to a total dose of 10 to 30 mg as necessary. Morphine administration is particularly helpful in acute pulmonary edema where it may promote peripheral arterial and venous dilatation. An important consideration when using intravenous nitrates is not to lower blood pressure to a level that would preclude adequate dosing of morphine.

Side effects of morphine administration, such as hypotension, can be minimized by keeping the patient supine and elevating the lower extremities if systolic pressure drops below 100 mm Hg. The concomitant use of atropine in 0.5 mg doses intravenously may be helpful in reducing the excessive vagomimetic effects of morphine if significant bradycardia or hypotension occurs. Although respiratory depression is relatively uncommon, the respiration rate should be monitored, particularly as cardiovascular status improves. The narcotic reversing agent naloxone, 0.4 to 2 mg intravenously every 3 minutes up to 10 mg, can reverse the effects of morphine should respiratory compromise occur. Nausea and vomiting as potential side effects of large doses of morphine may be treated with a phenothiazine.

Antiplatelet Agents

Aspirin

In the ISIS-2 trial,[34] aspirin reduced 35-day mortality by 23%. When aspirin was combined with streptokinase, the relative reduction in mortality was 42%. A meta-analysis demonstrated that aspirin reduced coronary reocclusion and recurrent ischemic events after fibrinolytic therapy with either streptokinase or alteplase.[35] The initial dose should be 162 to 325 mg, and it should be continued indefinitely at a daily dose of 75 to 162 mg. This dose has been found to be as effective as higher doses and with less toxicity.[36] Aspirin suppositories (300 mg) can be used safely for patients with severe nausea and vomiting or with severe upper gastrointestinal problems. In patients with true aspirin hypersensitivity (hives, nasal polyps, bronchospasm, or anaphylaxis), clopidogrel or ticlopidine may be substituted with at least equal effectiveness.[37] The use of ibuprofen or other NSAIDs may limit the cardioprotective effect of aspirin.

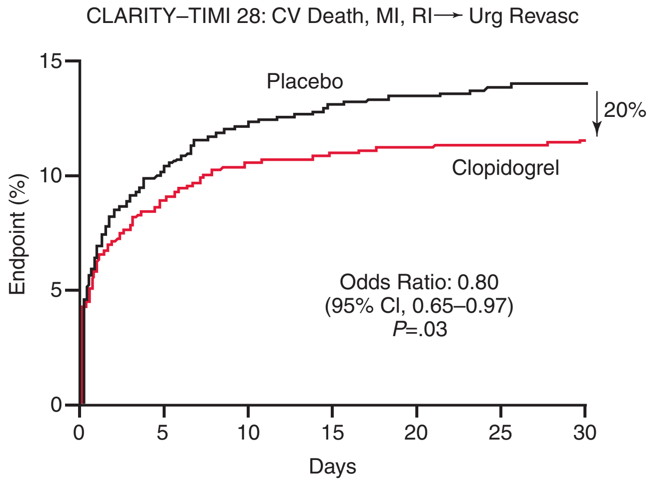

Figure 11–3 Cumulative incidence of the endpoint of death from cardiovascular causes, recurrent myocardial infarction, or recurrent ischemia leading to the need for urgent revascularization. The odds ratio for this endpoint was significantly lower in the clopidogrel group than in the placebo group at 30 days (11.6% versus 14.1%; odds ratio, 0.80 [95% confidence interval, 0.65 to 0.97]; *P* = 0.03). (Adapted from Sabatine MS, Cannon CP, Gibson CM, et al: Addition of clopidogrel to aspirin and fibrinolytic therapy for myocardial infarction with ST segment elevation. N Engl J Med 2005;352:1179-89, with permission.)

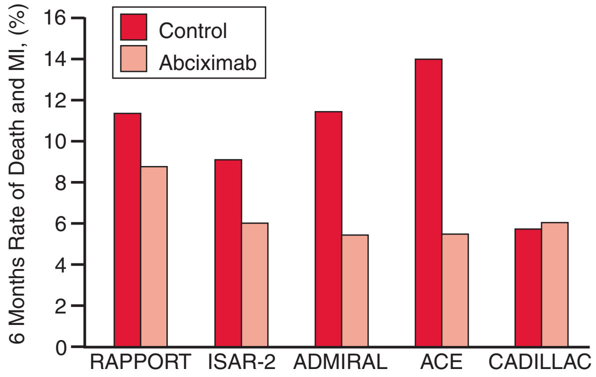

Figure 11–4 Rates of death and myocardial infarction (MI) at 6 months for five trials of primary percutaneous coronary intervention (PCI) with and without abciximab. (Adapted from Topol EJ, Neumann FJ, Montalescot G: A preferred reperfusion strategy for acute myocardial infarction. J Am Coll Cardiol 2003;42:1886-9, with permission.)

Clopidogrel

The COMMIT/CCS-2 trial[38] demonstrated a 13% reduction in death, MI, and stroke in medically managed patients treated within 12 hours of symptom onset with clopidogrel 75 mg daily. The CLARITY-TIMI 28 trial[39] demonstrated a 20% reduction in death, MI, and urgent revascularization in medically managed patients treated with a 300-mg loading dose of clopidogrel and a 75-mg daily maintenance dose as part of an early invasive strategy in patients <75 years old (Fig. 11–3). Neither trial showed an increase in major bleeding or intracranial hemorrhage. Therefore, patients should receive clopidogrel whether or not they are treated with PCI for at least 1 month (loading dose of 300 mg in patients <75 years of age who receive fibrinolysis and a loading dose of 75 mg in patients >75 years of age regardless of whether fibrinolysis is administered). It should be continued for at least 3 months after sirolimus drug-eluting stent implantation, 6 months after paclitaxel drug-eluting stent implantation, and up to 12 months in patients who are not at high risk for bleeding. For patients on clopidogrel in whom CABG is planned, the drug should be withheld for at least 5 days, and preferably for 7 days, unless the urgent need for revascularization outweighs the risk of excess bleeding.[40]

GP IIb/IIIa Inhibitors

Abciximab in combination with fibrinolytic therapy did not improve survival in two trials.[41,42] It did reduce reinfarction rates in patients <75 years old with anterior STEMI, but it increased ICH rates in older patients. Intravenous GP IIb/IIIa receptor inhibitors have also been studied as supportive antiplatelet therapy in patients who are undergoing PCI. Five randomized trials compared abciximab with placebo in patients who were undergoing primary PCI.[43-47] Treated patients had fewer adverse cardiac events (Fig. 11–4). The benefit appeared greater in patients treated before arrival at the cardiac catheterization laboratory because of higher initial patency rates.[45] Abciximab had greater benefit in patients receiving PTCA than stenting in the CADILLAC trial,[46] but decreased the risk of subacute stent thrombosis during follow-up. There are limited data on eptifibatide and tirofiban, but because of a similar mechanism of action, they may also be useful as antiplatelet therapy.

Antithrombin Agents

Unfractionated heparin (UFH) and low-molecular-weight heparin (LMWH) are antithrombins, and they decrease the rates of infarct artery reocclusion, deep venous thrombosis, pulmonary embolism, LV mural thrombus formation, and cerebral embolization. Anticoagulation is recommended in patients not receiving reperfusion therapy because data from the prefibrinolytic era demonstrate benefit in the absence of other interventions.[48]

Because streptokinase produces a systemic coagulopathy, additional antithrombin therapy with UFH offers only the small advantage of five lives saved per 1000 patients treated at a cost of one to two hemorrhagic strokes and three to five systemic bleeds (Fig. 11–5).[48] Therapy is most useful in patients at high risk for systemic embolism including those patients with large or anterior MI, atrial fibrillation, previous embolism, or known LV thrombus. With fibrin-specific agents (alteplase, reteplase, tenecteplase), UFH should be given intravenously with an aPTT target of 1.5 to 2.0 times control (50 to 70 seconds). A 60 U/kg bolus followed by a maintenance infusion of 12 U/kg per hour (with a maximum of 4000 U bolus and 1000 U/hour initial infusion for patients weighing >70 kg) is recommended. A bolus dose of 70 to 100 U/kg with a target activated clotting time of 300 seconds is recommended for primary PCI. The bolus dose should be reduced to 50 to 70 U/kg to achieve an ACT of 200 seconds when GP IIb/IIIa agents are used or rescue PCI is being performed.

The CREATE trial demonstrated that reviparin was superior to placebo in reducing the composite endpoint of death, MI, or stroke.[48a] LMWH can be considered an acceptable alternative to UFH as ancillary therapy to fibrinolysis, provided

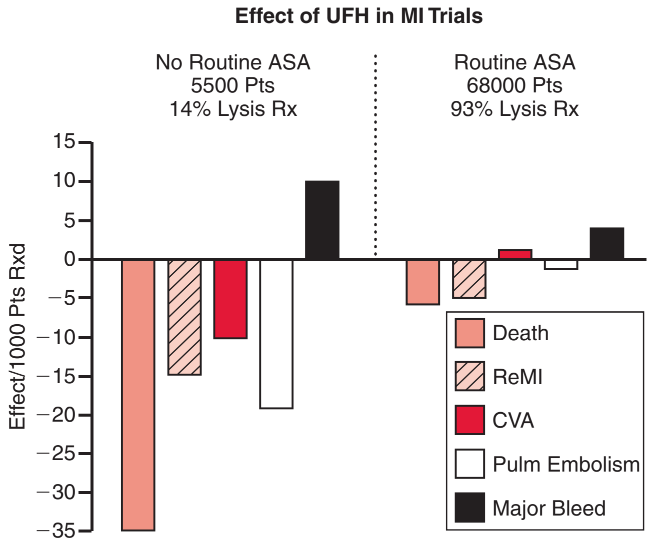

Figure 11–5 Effect of unfractionated heparin (UFH) in STEMI trials. The treatment effect of UFH/1000 patients is shown for trials without routine aspirin (ASA) *on the left* and with routine ASA *on the right.* Benefits of UFH are plotted *below the horizontal line* and harm is plotted *above the line.* CVA, cerebrovascular accident; Pulm Embolism, pulmonary embolism; ReMI, recurrent myocardial infarction; STEMI, ST-elevation myocardial infarction. (Adapted from data in Collins R, Peto R, Baigent C, Sleight P: Aspirin, heparin, and fibrinolytic therapy in suspected acute myocardial infarction. N Engl J Med 1997;336:847-60, with permission.)

significant renal dysfunction (serum creatinine >2.5 mg/dL in men or 2.0 mg/dL in women) is not present. Enoxaparin (30 mg intravenous bolus followed by 1.0 mg/kg subcutaneously every 12 hours until hospital discharge) used in combination with full-dose tenecteplase until recently was the most comprehensively studied regimen in patients <75 years of age.[42] However, older patients have an unacceptable excess rate of ICH with this dose.[49] The ExTRACT-TIMI 25 trial tested a reduced dose of enoxaparin (no intravenous bolus; maintenance dose of 0.75 mg/kg every 12 hours) in elderly patients.[49a] When combined with clopidogrel, LMWH is associated with significantly improved rates of angiographic patency and lower rates of death/MI compared with UFH.[50] In ExTRACT-TIMI 25, there was a 17% relative risk reduction in the composite endpoint of death or nonfatal reinfarction and a 19% relative risk reduction in the composite endpoint of death or nonfatal reinfarction or urgent revascularization with enoxaparin compared with unfractionated heparin ($P < 0.001$) (Fig. 11–6).[49b] Major bleeding occurred in 2.1% and 1.4% of the enoxaparin and unfractionated heparin groups, respectively ($P < 0.001$). The direct thrombin inhibitor bivalirudin was not superior to UFH in patients receiving streptokinase,[51] but may be an option in patients with known heparin-induced thrombocytopenia who need anticoagulation.

The OASIS-6 trial evaluated the specific factor Xa antagonist fondaparinux (2.5 mg subcutaneously daily) in 12,092 patients with STEMI.[51a] The trial design compared fondaparinux given for up to 8 days versus placebo in patients when the treating physician felt UFH was not indicated (stratum I) and versus unfractionated heparin for 48 hours when the treating physician felt UFH was indicated (stratum II). The primary endpoint, death, or reinfarction, occurred in 14% of placebo patients and 11.2% of fondaparinux patients in stratum I (HR 0.79; 0.68-0.92), and in 8.7% of UFH patients and 8.3% of fondaparinux patients (HR 0.96; 0.81-1.13) in stratum II. Thus, fondaparinux was superior to placebo (stratum I) but yielded similar results to those achieved with UFH (stratum II). The outcome of patients in stratum II who underwent PCI tended to be worse when fondaparinux was used. Severe hemorrhage occurred in 1.3% of control patients and 1.0% of fondaparinux patients through nine days (p = 0.13). While the convenience of once-daily subcutaneous injections of fondaparinux may be attractive compared with UFH, the need for co-administration of an additional antithrombin with antiIIa activity if a PCI is performed in a patient treated with fondaparinux complicates its use.[51b] Further information regarding the appropriate dosing of additional antithrombins along with fondaparinux in the catheterization laboratory, as well as additional information regarding the benefits and risks of fondaparinux across a broad range of fibrinolytics, is needed before its role in the management of STEMI can be properly established.

β-Blockers

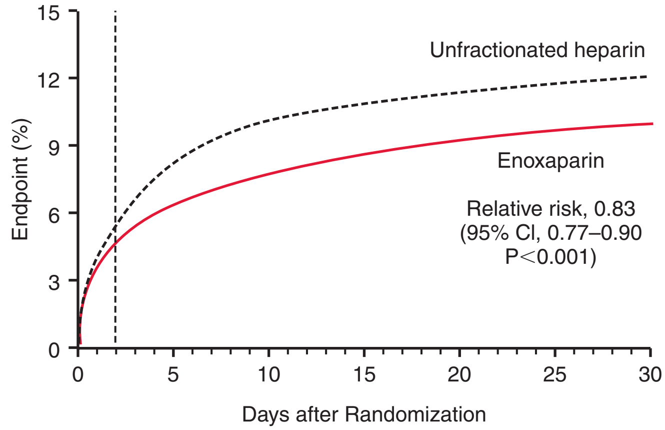
β-Blockers diminish myocardial oxygen demand by reducing heart rate, systemic arterial pressure, and myocardial contractility. Reduction in the heart rate prolongs the diastolic period and may augment perfusion to the subendocardium. In patients not receiving fibrinolytic therapy, early trials suggested reduction in infarct size[52] and mortality.[53,54] In patients receiving fibrinolytic therapy, trials have not found a mortality reduction,[55,56] although recurrent ischemia and reinfarction rates were reduced. It has also been suggested that β-blockers decrease ventricular arrhythmias and decrease the risk of intracerebral hemorrhage with lytic therapy. Therefore, it is reasonable to give early intravenous β-blockade to STEMI patients without contraindications, followed by oral therapy.

Intravenous metoprolol is given in three 5 mg doses over 15 minutes, followed by a 25 to 50 mg oral dose 15 minutes later and every 6 hours for 48 hours, before twice daily administration of 50 to 100 mg. Intravenous atenolol is given as two 5 mg doses 15 minutes apart. Then, 50 mg is given orally 15 minutes later, followed by another 50 mg in 12 hours and then 50 to 100 mg daily. Contraindications to the use of early intravenous and oral β-blockade include heart rate <60 beats per minute, systolic arterial pressure <100 mm Hg, uncompensated CHF or cardiogenic shock, PR interval >24 seconds, second or third degree AV block, active asthma or reactive airways disease, and cocaine use. If bradycardia or hypotension occurs with therapy, isoproterenol 1 to 5 mcg/min can be administered. Administration of early β-blocker therapy to patients with pump failure increases mortality rates.[38a]

Reperfusion Therapy

General Concepts

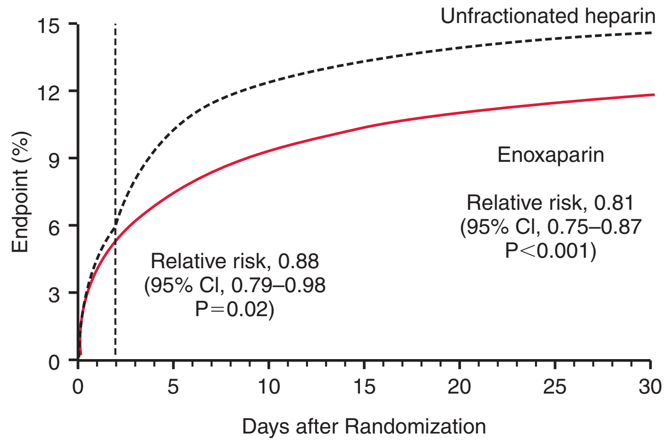
All STEMI patients should undergo rapid evaluation for reperfusion therapy and have a reperfusion strategy implemented promptly after contact with the medical system. Although rapid spontaneous reperfusion of the occluded infarct artery may occur, restoration of flow usually requires either fibrinolytic therapy or PCI. Many comparisons of these two reperfusion strategies have treated them as competing



A

No. at Risk

Unfractionated heparin	10,223	9,385	9,188	9,109	9,064	9,027	8,994
Enoxaparin	10,256	9,595	9,460	9,362	9,301	9,263	9,234



B

No. at Risk

Unfractionated heparin	10,223	9,174	8,955	8,868	8,818	8,775	8,738
Enoxaparin	10,256	9,479	9,312	9,200	9,130	9,084	9,052

Figure 11–6 Cumulative incidence of the primary endpoint (**A**) and the secondary endpoint (**B**). In **A,** the rate of the primary endpoint (death or nonfatal myocardial infarction) at 30 days was significantly lower in the enoxaparin group than in the unfractionated heparin group (9.9% versus 12.0%, $P < 0.001$ by the log-rank test). The *dashed vertical line* indicates the comparison at day 2 (direct pharmacologic comparison), at which time a trend in favor of enoxaparin was seen. In **B,** the rate of the main secondary endpoint (death, nonfatal myocardial infarction, or urgent revascularization) at 30 days was significantly lower in the enoxaparin group than in the unfractionated heparin group (11.7% versus 14.5%, $P < 0.001$ by the log-rank test). The difference was already significant at 48 hours (6.1% in the unfractionated heparin group versus 5.3% in the enoxaparin group, $P = 0.02$ by the log-rank test). The interval shown is the time (in 24-hour intervals) from randomization to an event or the last follow-up visit. CI, confidence interval. (Adapted from Antman EM, Morrow DA, McCabe CH, et al., for the ExTRACT-TIMI 25 Investigators: Enoxaparin versus unfractionated heparin with fibrinolysis for ST-Elevated Myocardial Infarction. N Engl J Med 2006;354:1477-88, with permission.)

options with little consideration of an interface between them (Fig. 11–7). Early, complete, and sustained infarct artery patency is a key determinant of both short- and long-term prognosis regardless of whether reperfusion is accomplished by fibrinolysis[23] or by PCI.[57] Therefore, every effort should be made to shorten the time from symptom onset to contact with the medical system and to implement a reperfusion strategy using the concept of medical system goals. These include a door-to-needle (or EMS-to-needle) time for fibrinolytic therapy within 30 minutes or a door-to-balloon (or EMS-to-balloon) time for PCI within 90 minutes. These goals should not be understood as *ideal* times, but rather the longest times that should be considered acceptable in every appropriate patient unless there is a good reason for delay, such as uncertainty about the diagnosis, need for the evaluation and treatment of other life-threatening conditions (e.g., respiratory failure), or delays associated with the patient's informed choice to consider therapy.

Even when fibrinolysis or PCI is successful in restoring infarct artery flow, perfusion of the infarct zone may still be compromised by a combination of microvascular damage and reperfusion injury.[58] Microvascular damage results from downstream thrombus embolization followed by the release of substances from activated platelets that promote microvascular spasm. Reperfusion injury results in cellular edema, free radical formation, calcium overload, and acceleration of apoptosis. Additionally, cytokine activation in the infarct zone leads to neutrophil accumulation and inflammatory mediators that contribute to tissue injury. Thus, adjunctive and ancillary treatments that minimize the amount of microvascular damage and also protect the jeopardized myocardial infarct zone are needed for more successful tissue-level reperfusion.

Four variables should be considered in selecting the type of reperfusion therapy (1) time from symptom onset; (2) risk of STEMI; (3) risk of fibrinolysis; and (4) predicted door-to-balloon time.

Time from Symptom Onset

Fibrinolytic therapy administered within the first two (especially the first) hours can occasionally abort MI and dra-

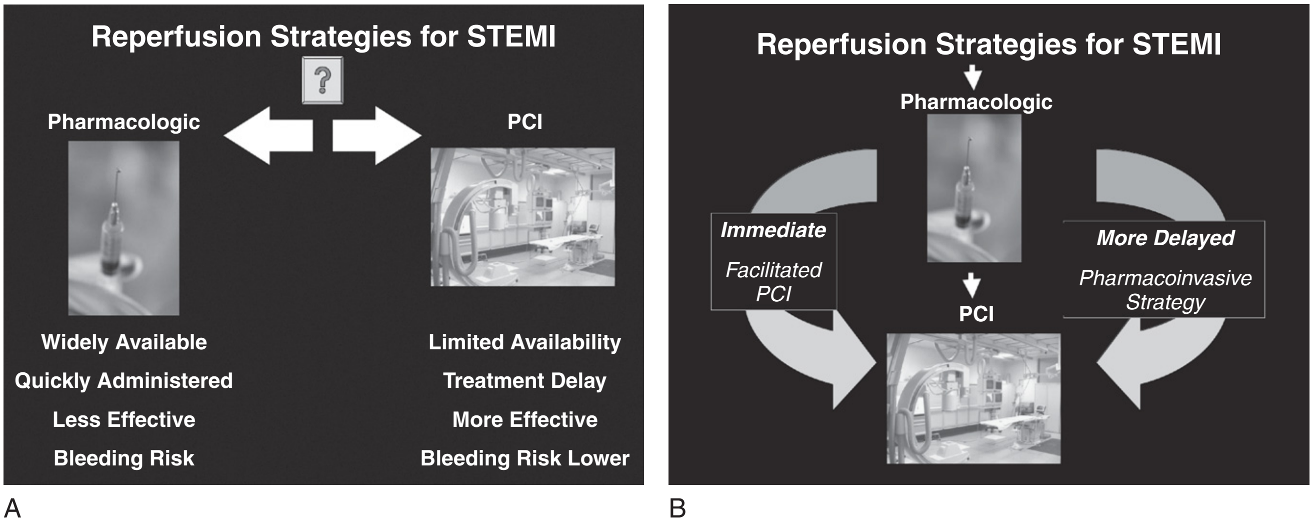


Figure 11–7 Reperfusion strategies for ST-elevation myocardial infarction (STEMI). **A,** Strategies where fibrinolytic therapy is selected versus percutaneous coronary intervention (PCI). **B,** Strategies where a pharmacologic regimen is given before PCI.

matically reduces mortality rates.[22,23] Prehospital fibrinolysis reduces treatment delays by up to 1 hour, allowing the majority of patients to be treated within 2 hours of symptom onset, and reduces mortality rates by 17% compared with therapy initiated in the hospital.[59] However, the efficacy of fibrinolytic agents in lysing thrombus diminishes with increasing treatment delays.[60] In contrast, PCI can seldom be performed within 2 hours of symptom onset, but reperfusion rates are superior to fibrinolytic therapy and independent of time. Although the CAPTIM[61] and PRAGUE-2[62] studies reached different conclusions about the overall superiority of PCI over fibrinolysis, similar results were seen in time-to-treatment subset analyses. Patients treated within 2 hours of symptom onset in CAPTIM had improved outcomes with prehospital tPA versus transfer for PCI.[63] Patients treated within 3 hours of symptom onset in PRAGUE-2 had equivalent mortality rates whether treated with streptokinase or transferred for PCI.[62] Conversely, both studies showed superior outcomes with PCI in patients with symptom duration >3 hours.

Risk of STEMI

Different risk stratification tools are available to quantify risk.[64,65] Patients with low mortality risk have similar outcomes with fibrinolysis or PCI.[66,67] Patients with anterior STEMI,[66,67] older age, congestive heart failure,[68] or cardiogenic shock[69] have better outcomes with PCI. The point of equipoise between strategies is an estimated 30-day mortality risk of 3%.[70]

Risk of Bleeding

The higher the risk of bleeding with fibrinolytic therapy, the more PCI would be favored as the reperfusion strategy. The increased risk for ICH in the elderly is a strong factor that favors PCI in this subgroup.

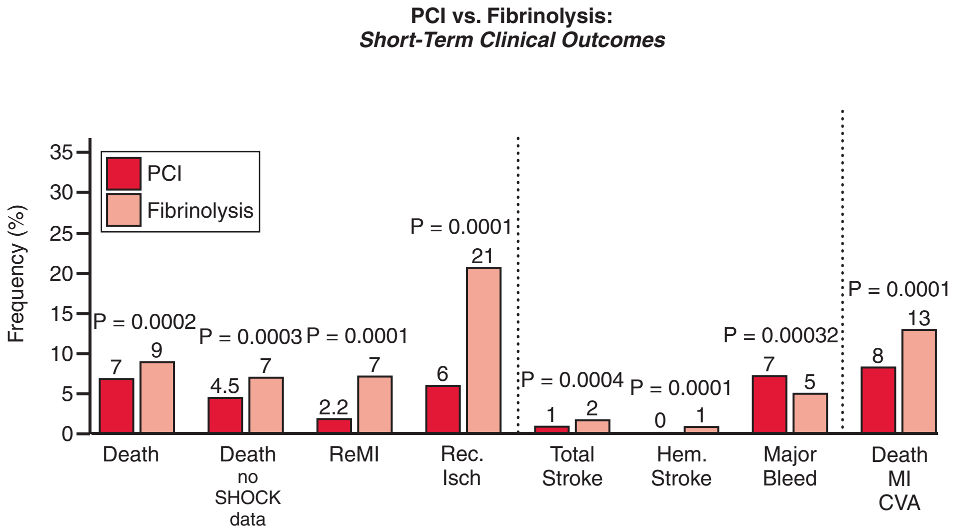
Predicted Door-to-Balloon Time

PCI is superior to fibrinolytic therapy when it can be performed expeditiously by experienced teams in high-volume hospitals.[71] The benefit noted in the randomized clinical trials[72] (Fig. 11–8) was strongly influenced by a reduction of nonfatal recurrent MI. This benefit was likely exaggerated by protocols that strongly discouraged rescue PCI when fibrinolysis failed or cardiac catheterization for recurrent ischemia after initially successful fibrinolysis. Nevertheless, stroke and mortality rates were lower with PCI, and clinical experience supports less complicated hospitalizations and fewer hospital days for these patients. However, complication rates are higher for patients who present after routine working hours,[73] and lower mortality rates with PCI have not been demonstrated in low-volume hospitals.[71,74] In hospitals without PCI capability, the reperfusion therapy choice is fibrinolytic therapy or transfer to a PCI center. Because the mortality benefit associated with PCI over fibrinolysis decreases as time-to-treatment differences increase,[75] the PCI strategy may not reduce mortality when a treatment delay >60 minutes is anticipated (Fig. 11–9). In the United States, only 4% of transfer patients are treated with PCI within 90 minutes and the average time to treatment is 3 hours.[76] Therefore, STEMI patients who present to a facility that does not have the capability for expert, prompt intervention with primary PCI within 90 minutes of first medical contact should undergo fibrinolysis unless contraindicated.[2] Clinical circumstances in which fibrinolytic therapy or PCI are generally preferred are shown in Table 11–1.

Fibrinolytic Therapy

Indications and Contraindications

In the absence of contraindications, fibrinolytic therapy should be administered to STEMI patients with symptom onset within the prior 12 hours and ST elevation >0.1 mV in at least two contiguous leads or new, or presumably new, LBBB. Patients with true posterior MI and patients with symptom duration for 12 to 24 hours and ST elevation are also reasonable candidates. Contraindications and cautions for using fibrinolytic therapy are shown in Table 11–2. Hemorrhage is the most critical risk, especially intracranial hemorrhage which is fatal in more than one half of patients. Several models for estimating the risk of ICH after fibrinolysis have been developed.[77-79] Patients with >4% risk of ICH should be treated with PCI rather than fibrinolytic therapy. Streptokinase without heparin has the lowest ICH rate.



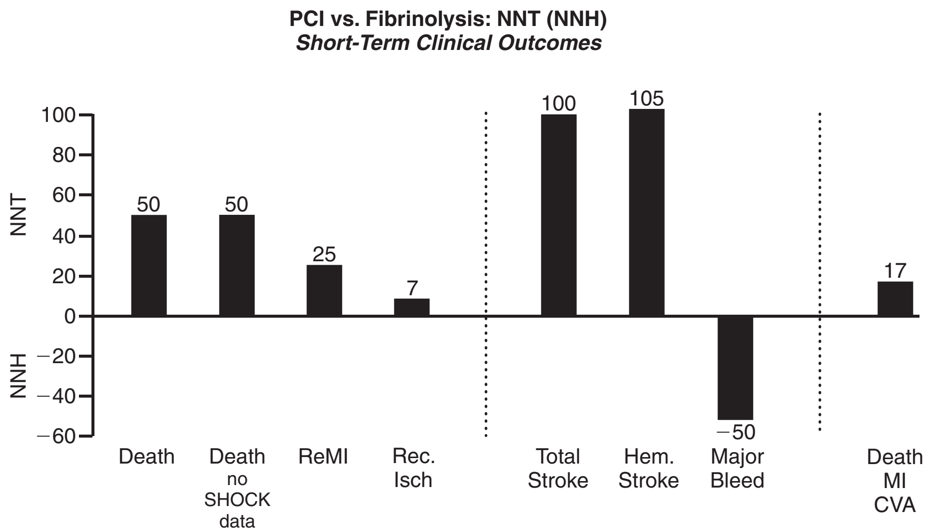


Figure 11–8 Percutaneous coronary intervention (PCI) versus fibrinolysis for ST-elevation myocardial infarction (STEMI). The short-term (4 to 6 weeks) (*top left*) and long-term (*top right*) outcomes for the various endpoints shown are plotted for patients with STEMI randomized to PCI or fibrinolysis for reperfusion in 23 trials ($N = 7739$). Based on the frequency of events for each endpoint in the two treatment groups, the number needed to treat (NNT) or number needed to harm (NNH) is shown for the short-term (*bottom left*) and long-term (*bottom right*) outcomes. The magnitude of the treatment differences for death, nonfatal reinfarction, and stroke vary depending on whether PCI is compared with streptokinase or a fibrin-specific lytic. For example, when primary PCI is compared with alteplase (tPA) and the SHOCK trial is excluded, the mortality rate is 5.5% versus 6.7% (OR 0.81, 95% CI 0.64 to 1.03, $P = 0.081$). CVA, cerebrovascular accident; Hem. Stroke, hemorrhagic stroke; MI, myocardial infarction; Rec. Isch, recurrent ischemia; ReMI, recurrent MI. (Adapted from Keeley EC, Boura JA, Grines CL: Primary angioplasty versus intravenous thrombolytic therapy for acute myocardial infarction: A quantitative review of 23 randomised trials. Lancet 2003;361:13-20, with permission.)

Mortality Benefit

Placebo controlled trials have demonstrated the survival benefit associated with fibrinolytic therapy.[34,80-82] Mortality reduction is greatest within the first few hours of symptoms, especially the first hour, due to salvage of ischemic myocardium with reduced infarct size. The mortality benefit that is seen with later treatment is more dependent on improved infarct healing and myocardial remodeling, on reduced electrical heterogeneity, and on the reduced potential for life-threatening ventricular arrhythmia. Patients with LBBB, anterior MI, hypotension, and tachycardia have higher risk from STEMI and achieve greater therapeutic benefit.[22] The patient risk and potential therapeutic benefit in inferior MI are increased with right ventricular involvement, precordial ST depression, or complete heart block.[83] The number of ECG leads involved and the extent of ST deviation is an excellent predictor of potential STEMI risk.[28] Although patients more than 75 years of age might better be treated with PCI, the absolute number of lives saved per 1000 patients treated with fibrinolytic therapy compared with placebo is actually greater than in younger patients (34 versus 28).[84]

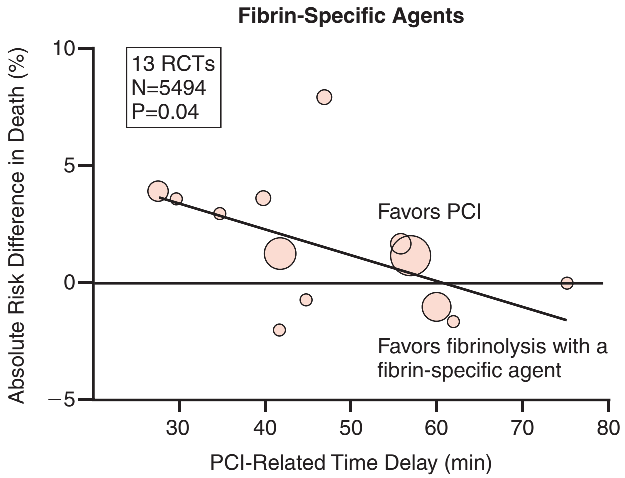

Figure 11–9 PCI versus lysis with fibrin-specific agents: Is timing (almost) everything? RCT, randomized controlled trial; N, number of patients; PCI, percutaneous coronary intervention. (Adapted from Nallamothu BK, Bates ER: Percutaneous coronary intervention versus fibrinolytic therapy in acute myocardial infarction: Is timing (almost) everything? Am J Cardiol 2004;94:772-4, with permission.)

Effect on LV Function

Successful early reperfusion reduces infarct size, preserves regional wall motion, decreases ventricular dilation, and maintains global left ventricular function—an important predictor of survival. Restoration of normal infarct artery flow does not reflect microvascular reperfusion, which is better evaluated by myocardial blush on angiography, contrast perfusion on echocardiography, or prompt resolution of ST elevation on electrocardiography. Poor microvascular reperfusion is associated with increased infarct size, morbidity, and mortality.

Complications

The major complication of fibrinolytic therapy is hemorrhage which may or may not require transfusion. Risk factors include older age, female gender, lower body weight, and hypertension. Intracerebral hemorrhage encompasses parenchymal hemorrhage, intraventricular hemorrhage, subarachnoid hemorrhage, subdural hematoma, and epidural hematoma. Typical presenting features include an acute change in level of consciousness, unifocal or multifocal neurologic signs, coma, headache, nausea, vomiting, and seizures. The occurrence of a change in neurologic status during or after reperfusion therapy, particularly within the first 24 hours after initiation of treatment, is considered to be due to ICH until proved otherwise (Fig. 11–10). Fibrinolytic, antiplatelet, and anticoagulant therapies should be discontinued until a brain imaging scan shows no evidence of ICH. Neurology and/or neurosurgery consults should be obtained as dictated by clinical circumstances. Immediate measures to reduce intracranial pressure include mannitol infusion, elevation of the head of the bed to 30 degrees, endotracheal intubation, and hyperventilation to achieve a P_{CO_2} of 25 to 30 mm Hg. Cryoprecipitate (10 U) will increase the fibrinogen level by approximately 0.70 g/liter and the factor VIII level by approximately 30% in a 70-kg adult. Fresh frozen plasma restores factors V and VIII levels. Protamine (1 mg/100 U of UFH given in the preceding 4 hours) reverses heparin anticoagulation. Platelet transfusions (6 to 8 units) can be given if the bleeding time is abnormal. Blood pressure and blood glucose levels should be optimized. Neurosurgical evacuation of ICH may be required in select patients.[85]

Table 11–1 Assessment of Reperfusion Options for Patients with STEMI

Step 1: Assess Time and Risk

- Time since onset of symptoms
- Risk of STEMI
- Risk of fibrinolysis
- Time required for transport to a skilled PCI lab

Step 2: Determine if Fibrinolysis or an Invasive Strategy is Preferred

If presentation is <3 hours and there is no delay to an invasive strategy, there is no preference for either strategy.

Fibrinolysis is generally preferred if

- Early presentation (≤3 hours from symptom onset) and delay to invasive strategy (see below)
- Invasive Strategy is not an option
  - Catheterization lab occupied/not available
  - Vascular access difficulties
  - Lack of access to a skilled PCI lab†‡
- Delay to Invasive Strategy
  - Prolonged transport
  - Door-to-Balloon–Door-to-Needle time is >1 hour*§
  - Medical Contact-to-Balloon or Door-to-Balloon time is >90 minutes

An invasive strategy is preferred if

- Skilled PCI lab available with surgical back-up†‡
  - Medical Contact-to-Balloon or Door-to-Balloon time is <90 minutes
  - Door-to-Balloon—Door-to-Needle time is <1 hour*
- High Risk from STEMI
  - Cardiogenic shock
  - Killip class is ≥3
- Contraindications to fibrinolysis including increased risk of bleeding and ICH
- Late presentation
  - The symptom onset was > 3 hours ago
- Diagnosis of STEMI is in doubt

*Applies to fibrin-specific agents.
†Operator experience > a total of 75 primary PCI cases/year.
‡Team experience > a total of 36 primary PCI cases/year.
§This calculation implies that the estimated delay to the implementation of the invasive strategy is >1 hour versus initiation of fibrinolytic therapy immediately with a fibrin-specific agent.
ICH, intracranial hemorrhage; PCI, percutaneous coronary intervention; STEMI, ST-elevation myocardial infarction.
Modified from Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction). Circulation 2004;110:588-636.

Comparison of Fibrinolytic Agents

Fibrinolytic agents are plasminogen activators. Plasmin dissolves the fibrin mesh that holds red blood cells and platelets together as a thrombus. The four approved intravenous agents are compared in Table 11–3. Alteplase is superior

Table 11–2 Contraindications and Cautions for Fibrinolysis in STEMI*

Absolute Contraindications

- Any prior ICH
- Known structural cerebral vascular lesion (e.g., atrioventricular malformation)
- Known malignant intracranial neoplasm (primary or metastatic)
- Ischemic stroke within 3 months EXCEPT acute ischemic stroke within 3 hours
- Suspected aortic dissection
- Active bleeding or bleeding diathesis (excluding menses)
- Significant closed head or facial trauma within 3 months

Relative Contraindications

- History of chronic, severe, poorly controlled hypertension
- Severe uncontrolled hypertension on presentation (SBP > 180 or DBP > 110 mm Hg)†
- History of prior ischemic stroke >3 months, dementia, or known intracranial pathology not covered in contraindications
- Traumatic or prolonged (>10 minutes) CPR or major surgery (<3 weeks)
- Recent (within 2-4 weeks) internal bleeding
- Noncompressible vascular punctures
- For streptokinase/anistreplase: prior exposure or prior allergic reaction to these agents
- Pregnancy
- Active peptic ulcer
- Current use of anticoagulants: the higher the INR, the higher the risk of bleeding

*Viewed as advisory for clinical decision-making and may not be all-inclusive or definitive.
†Could be an absolute contraindication in low-risk patients with myocardial infarction.
CPR, cardiopulmonary resuscitation; DBP, diastolic blood pressure; ICH, intracranial hemorrhage; INR, international normalized ratio; SBP, systolic blood pressure.
Modified from Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction). Circulation 2004;588-636.

to streptokinase in reducing morbidity and mortality, but is more expensive and confers a slightly higher risk of ICH.[86] Bolus dosing with reteplase[87] or tenecteplase[88] produces equivalent results compared with alteplase. The cost-benefit ratio is more favorable for the expensive agents in patients with a large myocardial area of risk and a low risk of ICH. Streptokinase is used by some clinicians when predicted infarct size is small or ICH risk is higher, but should not be reused because of the high prevalence of neutralizing antibody titers.

Percutaneous Coronary Intervention

Primary PCI

More than 90% of STEMI patients are candidates for primary PCI. Patency rates >90% and TIMI-3 flow rates of 70% to 90% have been reported. If immediately available, primary PCI should be performed in patients with STEMI (including true posterior MI) or MI with new or presumably new LBBB, who can undergo PCI of the infarct artery within 12 hours of symptom onset (or more than 12 hours if ischemic symptoms persist)—if performed in a timely fashion (balloon inflation within 90 minutes of presentation) by persons skilled in the procedure (i.e., clinicians who perform more than 75 PCI procedures per year). The procedure should be supported by experienced personnel in an appropriate laboratory environment (that performs more than 200 PCI procedures per year, of which at least 36 are primary PCI for STEMI, and has cardiac surgery capability).[2]

Randomized clinical trials performed in selected patients by experienced providers demonstrated that PCI-treated patients experience lower short-term mortality rates (5.0% versus 7.0%, RR 0.70, 95% CI 0.58 to 0.85, $P = 0.0002$), less non-fatal reinfarction (3.0% versus 7.0%, RR 0.35, 95% CI 0.27 to 0.45, $P = 0.0003$), and less hemorrhagic stroke (0.05% versus 1.0%, RR 0.05, 95% CI 0.006 to 0.35, $P = 0.0001$) than those treated by fibrinolysis, but with an increased risk for major bleeding (7.0% versus 5.0%, RR 1.3, CI 1.02 to 1.65, $P = 0.032$) (see Fig. 11–8).[72] The efficacy differences are smaller when PCI is compared with alteplase, the invasive strategy is allowed after fibrinolytic therapy, patients are treated by less-experienced operators or in low-volume laboratories, or door-to-balloon times are excessively prolonged.

The survival benefit with PCI is time dependent (Fig. 11–11). To reproduce the outcomes in the randomized trials where PCI was performed by experienced operators with an additional mean treatment delay of 40 minutes for PCI instead of fibrinolytic therapy, strict performance criteria must be followed. These include door-to-balloon times <90 minutes, TIMI 2/3 flow rates in more than 90% of patients, emergency bypass surgery rates <2%, and performance of PCI in more than 85% of patients brought to the laboratory. Risk-adjusted hospital mortality rates should be <7% in patients without cardiogenic shock, which would be comparable with those reported for fibrinolytic therapy[72] and consistent with previously reported registry results where mortality rates were not different between treatment strategies.[25,89-91] If the performance criteria stated above cannot be met, fibrinolytic therapy should be considered unless it is contraindicated.

PCI has its greatest mortality benefit in high-risk patients. PCI has been associated with an absolute 9% reduction in 30-day mortality in cardiogenic shock[69] and a 33% relative risk reduction (versus 9% with fibrinolytic therapy) in congestive heart failure.[68] Compared with fibrinolytic therapy, PCI reduces mortality in patients with anterior MI, but there is no difference in patients with nonanterior MI.[66,67] Reocclusion rates are 15% after PTCA and 5% after stenting, compared with 30% after fibrinolytic therapy.[92] Potential complications include problems with the arterial access site; adverse reactions to volume loading, contrast medium, and antithrombotic medications; technical complications; and reperfusion events.

Compared with PTCA, intracoronary stents achieve a better immediate angiographic result with a larger arterial lumen, less reocclusion and restenosis of the infarct artery, and fewer subsequent ischemic events, but there are no differences in mortality rates or reinfarction rates.[93]

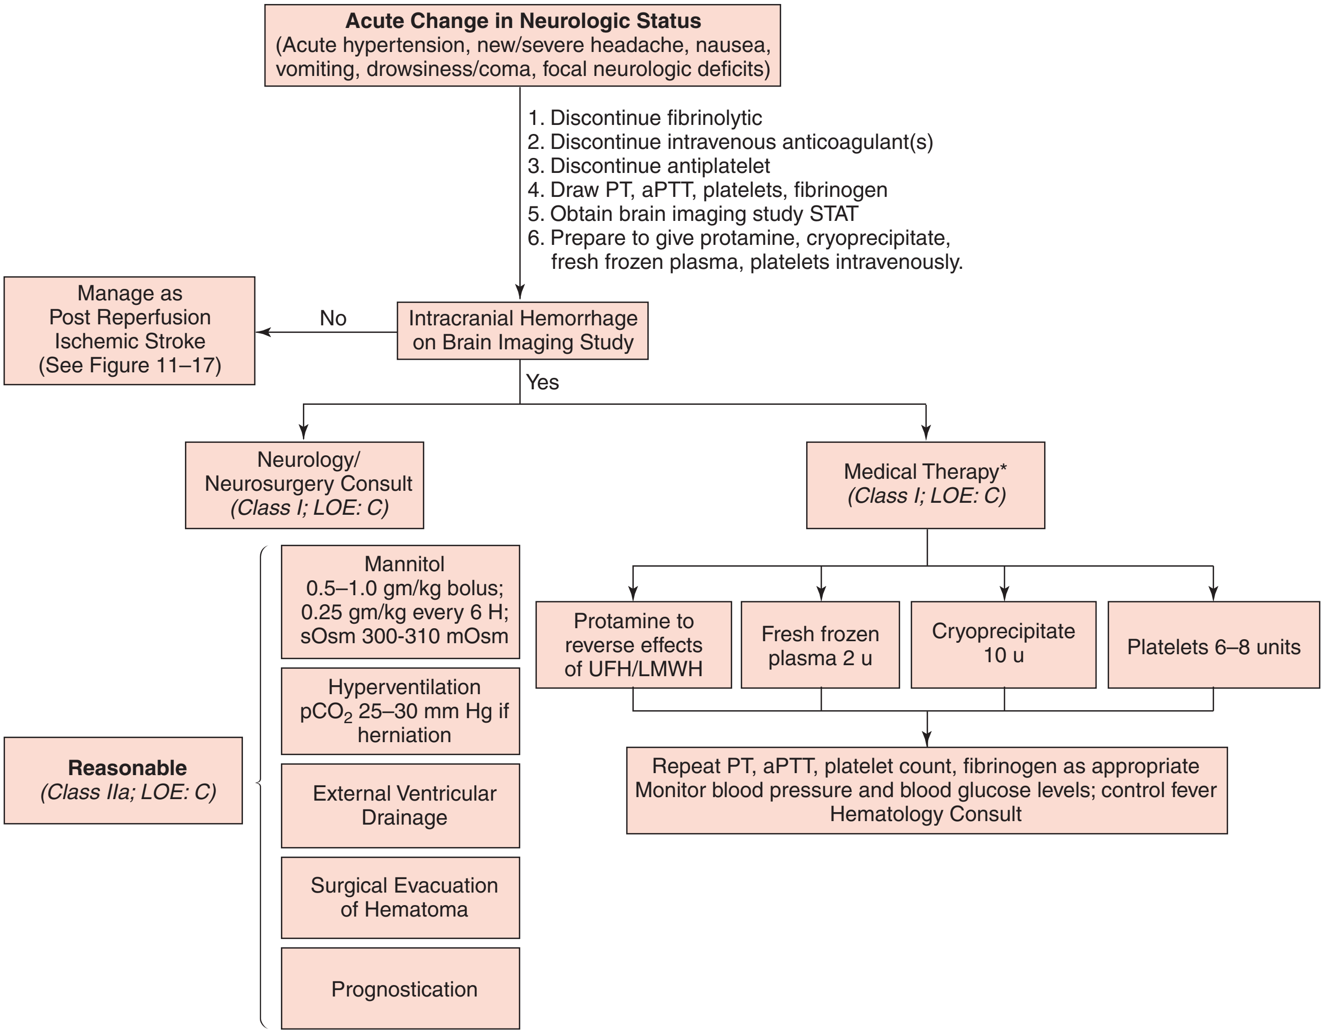

Figure 11–10 Algorithm for evaluation of intracranial hemorrhage complicating fibrinolytic therapy for ST-elevation myocardial infarction. *As dictated by clinical circumstances. aPTT, activated partial thromboplastin time; H, hours; LMWH, low-molecular-weight heparin; LOE, level of evidence; mOsm, milliosmoles; PT, prothrombin time; sOsm, serum osmolality; UFH, unfractionated heparin. Stroke 1997;28:1530-40, with permission.)

Rescue PCI

Intravenous fibrinolytic therapy fails to restore infarct artery patency in 25% to 50% of patients. Rescue PCI can restore patency in most of these patients. A major challenge, however, is identifying patients with unsuccessful fibrinolysis and treating them within a time frame where myocardial salvage is possible. Clinical markers of reperfusion, such as relief of ischemic-type chest discomfort, partial resolution of ST-segment elevation, and reperfusion arrhythmias, have limited predictive value in identifying failure of fibrinolysis.[94] Other limitations of rescue PCI include higher rates of procedural failure, microvasular no-reflow, hemorrhage, and reocclusion than with primary PCI.

Rescue PCI in patients with anterior STEMI was previously shown to reduce congestive heart failure and death rates when performed within 8 hours of symptom onset.[95] Subsequently, rescue PCI was shown to reduce the combined 6-month endpoint of death, reinfarction, stroke, or severe heart failure by 50% compared with repeat fibrinolytic therapy or medical management in a general population.[96] Rescue PCI should be performed in patients with cardiogenic shock or congestive heart failure and is reasonable in patients with large infarction and persistent ischemic symptoms. The benefit in low-risk patients may not exceed the increased risk of bleeding.

Facilitated PCI

Facilitated PCI refers to a strategy of planned immediate PCI after an initial pharmacologic regimen such as full-dose fibrinolytic therapy, half-dose fibrinolytic therapy, a GP IIb/IIIa inhibitor, or a combination of reduced-dose fibrinolytic therapy and platelet GP IIb/IIIa inhibitor (see Fig. 11–7B). This represents a linear approach to reperfusion strategies rather than an either/or approach. It should be differentiated from drug administration during primary PCI and from rescue PCI after unsuccessful fibrinolysis. The theory is that earlier reperfusion will decrease infarct size before PCI stabilizes the index lesion. However, preliminary studies[97,98] have not demonstrated reduced infarct size or improved outcomes, and increased bleeding is a possibility. The ASSENT-4 PCI trial[99] demonstrated lower mortality (3.6% versus 6.0%)

Table 11–3 Comparison of Approved Fibrinolytic Agents

	Streptokinase	Alteplase	Reteplase	Tenecteplase-tPA
Dose	1.5 MU over 30-60 min	Up to 100 mg in 90 min (based on weight)*	10 U × 2 each over 2 min	30-50 mg (based on weight)†
Bolus administration	No	No	Yes	Yes
Antigenic	Yes	No	No	No
Allergic reactions (hypotension most common)	Yes	No	No	No
Systemic fibrinogen depletion	Marked	Mild	Moderate	Minimal
90-min patency rates (approximate %)	50	75	75	75
TIMI grade 3 flow (%)	32	54	60	63
Cost (in dollars) per dose	$613	$2,974	$2,750	$2,833 for 50 mg

*Bolus 15 mg, infusion 0.75 mg/kg × 30 minutes (maximum 50 mg), then 0.5 mg/kg not to exceed 35 mg over the next 60 minutes to an overall maximum of 100 mg.
†30 mg for weight <60 kg; 35 mg for 60-69 kg; 40 mg for 70-79 kg; 45 mg for 80-89 kg; 50 mg for 90 kg or more.

for primary PCI as compared with full-dose tenecteplase plus immediate catheterization owing to fewer ischemic complications, rather than fewer bleeding complications. However, in hospitals without PCI capability, the strategy still holds promise for high-risk patients who have low bleeding risk and short symptom duration. It is unlikely to be of benefit to low-risk patients, patients with immediate access to a catheterization laboratory, or those with longer symptom duration.

Hospitals Without On-Site Cardiac Surgery

Whereas hospitals with onsite cardiac surgery can offer immediate access to a PCI laboratory, hospitals without this resource have to establish more complicated treatment protocols that include interhospital transfer agreements. Fibrinolytic therapy will usually be the primary reperfusion strategy. However, many patients are ineligible for fibrinolytic therapy because of bleeding risk and should be considered for transfer for primary PCI.[100] Patients who fail fibrinolysis and are candidates for rescue PCI should also be transferred, as should patients with congestive heart failure or cardiogenic shock.

Some hospitals with cardiac catheterization laboratories are able to offer PCI without on-site cardiac surgery. Several performance criteria must be met for this strategy to reproduce the favorable results in published reports[101,102] (Table 11–4). The operators must be experienced interventionalists performing at least 75 interventions per year, the laboratory must perform at least 36 procedures per year, and the nursing and technical staff must be fully trained. The full range of PCI equipment must be available, and intra-aortic balloon counterpulsation expertise is required. Appropriate case selection and continuous quality improvement are important components (Table 11–5). High-risk patients should be transferred to a hospital with on-site surgery for primary PCI.

The concept of interhospital transfer for primary PCI versus on-site fibrinolytic therapy has been tested in five reports (Fig. 11–12).[62,103-106] The favorable results[107] were similar to those reported for primary PCI without interhospital transfer.[72] However, transfer times were short because of patient selection and a centrally organized emergency transportation system. To reproduce these results, the time from arrival at the first hospital door-to-balloon inflation in the

Table 11–4 Criteria for the Performance of Primary PCI at Hospitals Without On-Site Cardiac Surgery

- The operators must be experienced interventionalists who regularly perform elective PCI at a surgical center (at least 75 cases/year). The catheterization laboratory must perform a minimum of 36 primary PCI procedures per year.
- The nursing and technical catheterization laboratory staff must be experienced in handling acutely ill patients and comfortable with interventional equipment. They must have acquired experience in dedicated interventional laboratories at a surgical center. They participate in a 24-hour, 365-day call schedule.
- The catheterization laboratory itself must be well equipped, with optimal imaging systems, resuscitative equipment, IABP support, and must be well-stocked with a broad array of interventional equipment.
- The cardiac care unit nurses must be adept in hemodynamic monitoring and IABP management.
- The hospital administration must fully support the program and enable the fulfillment of the above institutional requirements.
- There must be formalized written protocols in place for immediate and efficient transfer of patients to the nearest cardiac surgical facility that are reviewed/tested on a regular (quarterly) basis.
- Primary PCI must be performed routinely as the treatment of choice around the clock for a large proportion of patients with STEMI to ensure streamlined care paths with increased case volumes.
- Case selection for the performance of primary PCI must be rigorous. Criteria for the types of lesions appropriate for primary PCI and for the selection for transfer for emergent aortocoronary bypass surgery are shown in Table 11–5.
- There must be an ongoing program of outcomes analysis and formalized periodic case review.

Institutions should participate in a 3- to 6-month period of implementation during which time development of a formalized primary PCI program is instituted that includes establishing standards, training staff, detailed logistic development, and creation of a quality assessment and error management system.

IABP, intra-aortic balloon pump; PCI, percutaneous coronary intervention; STEMI, ST-elevation myocardial infarction. Modified from Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction). Circulation 2004;110:588-636.

second hospital should be as short as possible, with a goal within 90 minutes. This goal is possible in the United States,[108] but remains unusual.[76] Directly transporting patients to PCI centers rather than transporting them to the nearest hospital may be a superior strategy to decrease time-to-treatment for primary PCI.

Table 11–5 Patient Selection for Primary PCI and Emergent Aortocoronary Bypass at Hospitals Without On-Site Cardiac Surgery

Avoid Intervention in Hemodynamically Stable Patients with

- Significant (≥60%) stenosis of an unprotected left main coronary artery upstream from an acute occlusion in the left coronary system that might be disrupted by the angioplasty catheter
- Extremely long or angulated infarct-related lesions with TIMI grade 3 flow
- Infarct-related lesions with TIMI grade 3 flow in stable patients with three-vessel disease
- Infarct-related lesions of small or secondary vessels
- Hemodynamically significant lesions in other than the infarct artery

Transfer Patients for Emergency Aortocoronary Bypass Surgery

- After primary PCI of occluded vessels if high-grade residual left main or multivessel coronary disease with clinical or hemodynamic instability is present (preferably with intraaortic balloon pump support)

Modified from Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction). Circulation 2004;110:588-636.

The Early Invasive Strategy

Routine cardiac catheterization and subsequent revascularization for suitable anatomy is now recommended for patients with NSTEMI.[109] Routine PCI performed within days after failed fibrinolysis has been evaluated in small studies, but there are no convincing data showing benefit.[110] The Occluded Artery Trial is evaluating whether routine PCI improves clinical outcomes in asymptomatic high-risk patients with an occluded infarct artery after occurrence of STEMI.[111] Older trials have also failed to demonstrate benefit for routine PCI hours to days after successful fibrinolysis.[112] However, improved equipment, improved antiplatelet and anticoagulant strategies, and the use of coronary stents have increased PCI success rates and decreased complications in the modern interventional cardiology era. Several reports now support this protocol, which has been referred to as a pharmacoinvasive strategy (see Fig. 11–7B).[113-116] Cardiac catheterization and revascularization for suitable anatomy should be performed in patients with spontaneous or provokable ischemia.[117]

HOSPITAL MANAGEMENT

Location

Patients should be admitted to the coronary care unit (CCU) when initial patient evaluation includes assessment of vital

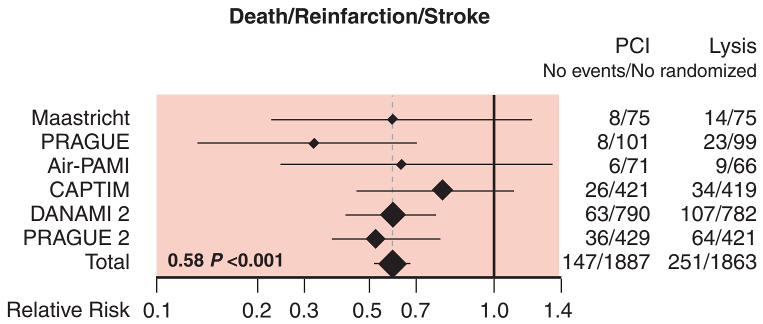

Figure 11–12 Relative risks for the composite of death, reinfarction, and stroke in 6 trials comparing transfer for primary PCI with immediate fibrinolysis for STEMI. (Adapted from Dalby M, Bouzamondo A, Lechat P, Montalescot G: Transfer for primary angioplasty versus immediate thrombolysis in acute myocardial infarction: A meta-analysis. Circulation 2003;108:1809-14, with permission.)

signs, pulse oximetry, cardiac rhythm and ST-segments, and symptoms of acute cardiac ischemia. Outstanding (and abnormal) laboratory results should be followed up, and standard admitting orders to the CCU should be implemented (Table 11–6). Intra-arterial and pulmonary artery pressure monitoring should be available for severely hypotensive patients. The intra-aortic balloon pump should be available for treatment of cardiogenic shock. Aspirin and β-blocker therapy in an adequate dose to control heart rate should be administered. Intravenous nitroglycerin is useful for control of angina, hypertension, or acute heart failure. Oxygen can be discontinued after 6 hours of patient stability if the oxygen saturation is >90%.

Nursing care should be provided by individuals certified in critical care with staffing based on the specific needs of patients and provider competencies, as well as organizational priorities. Patients should be monitored for the development of heart failure, serious arrhythmias, or recurrent ischemia. Medications such as stool softeners or anti-anxiety agents should be given based on nursing judgment. Terminal patients (no-code) or patients whose comorbidities make survival unlikely should not be admitted to the CCU.

Patients should be transferred to a monitored bed in a stepdown unit after 12 to 24 hours of clinical stability. Similarly, low-risk patients who have undergone successful PCI can be directly admitted to the stepdown unit for post-PCI care rather than to the CCU. Pulse oximetry, electrocardiographic monitoring, and defibrillation equipment should be available. The nursing staff should have a skill set similar to CCU nurses so that they may evaluate and respond to any clinical complications.

Routine Measures

Bed rest should be limited to 12 to 24 hours because of the concern about physical deconditioning and orthostatic hypotension. Patients should have no oral intake before a procedure, but otherwise should be prescribed the National Cholesterol Education Program's (NCEP) Adult Treatment Panel III (ATP III) Therapeutic Lifestyle Changes (TLC) diet focusing on the following: reduced intake of fats and cholesterol, <7% of total calories as saturated fats, <200 mg/day of cholesterol, increased consumption of omega-3 fatty acids, and appropriate caloric intake for energy needs.[7] Diabetic patients need an appropriate diet, and sodium intake should be restricted in patients with hypertension or heart failure. Patient counseling regarding risk factor modification that includes smoking cessation, medication compliance, diet, and exercise should be part of every patient encounter.

It is reasonable to use anxiolytic medications to alleviate short-term anxiety. Withdrawal of caffeine is associated with headache and increases in heart rate. One to two cups of coffee a day, enough to avert caffeine withdrawal, has not been associated with blood pressure increases or ventricular arrhythmias. Smokers may experience symptoms of nicotine withdrawal including anxiety, insomnia, depression, difficulty concentrating, irritability, anger, restlessness, and slowed heart rate. Anxiolytics, bupropion, and nicotine replacement therapy are treatment options. Intravenous haloperidol is a rapidly-acting neuroleptic that can be given to cardiac patients with agitation. Communication with the patient and family, liberalized visiting rules, psychological support, and counseling can decrease anxiety and depression for both the patient and the family members.

Medications

Nitroglycerin

Intravenous nitroglycerin is indicated in the first 48 hours after STEMI for treatment of persistent ischemia that responds to nitrate therapy, CHF, or hypertension. Intravenous, oral, or topical nitrates are useful beyond the first 48 hours after STEMI for treatment of recurrent angina or persistent CHF if their use does not preclude therapy with β-blockers or ACE inhibitors. The continued use of nitrate therapy beyond the first 24 to 48 hours in the absence of symptoms is not well established in contemporary practice. If sustained nitrate therapy is planned, a nitrate-free interval during daily dosing is important to avoid nitrate tolerance (see Chapter 5).

Antithrombotic Agents

Aspirin should be continued indefinitely, unless aspirin allergy exists.[36] Lower aspirin doses of 75 to 162 mg are preferred for long-term treatment because of a dose-dependent increase of bleeding risk. A thienopyridine should be substituted for aspirin when aspirin is contraindicated because of hypersensitivity or major gastrointestinal intolerance (see Chapter 5). Gastric side effects may be reduced by administration of H_2 antagonists, antacids, or use of enteric-coated aspirin. Available data suggest that dual antiplatelet therapy with both aspirin and clopidogrel should be continued for at least 1 month in all patients.[38,39] Clopidogrel 75 mg daily is generally preferred to ticlopidine 250 mg twice daily because of clopidogrel's fewer side effects and once daily dosing.

Intravenous UFH or LMWH should be used in most patients for at least 48 hours or longer if the clinical condition

Table 11–6 Sample Admitting Orders for the Patient with STEMI

Condition: Serious
IV: NS or D_5W to keep vein open. Start a second IV if IV medication is being given. This may be a heparin lock.
Vital signs: Every 30 min until stable, then every 4 h as needed. Notify physician if HR is <60 bpm or >100 bpm, systolic BP is <100 mm Hg or >150 mm Hg, respiratory rate is <8 breaths per minute or >22 breaths per minute.
Monitor: Continuous ECG monitoring for arrhythmia and ST-segment deviation.
Diet: NPO except for sips of water until stable. Then start 2 g sodium/d, low saturated fat (<7% of total calories/day), low cholesterol (<200 mg/day) diet, such as Therapeutic Lifestyle Changes (TLC) diet.
Activity: Bed rest and bedside commode and light activity when stable.
Oxygen: Continuous oximetry monitoring. Nasal cannula at 2 L/min. When stable for 6 h, discontinue oxygen and assess for oxygen need (i.e., O_2 saturation of <90%), and consider discontinuing oxygen.
Medications:
Nitroglycerin
- Use sublingual NTG 0.4 mg every 5 minutes as needed for chest discomfort.
- Intravenous NTG for CHF, hypertension, or persistent ischemia.

ASA
- If ASA not given in the ED, chew nonenteric-coated ASA† 162-325 mg.
- If ASA has been given, start daily maintenance of 75-162 mg. May use enteric-coated ASA for gastrointestinal protection.

β-Blocker
- If not given in the ED, assess for contraindications, i.e., bradycardia and hypotension. Continue daily assessment to ascertain eligibility for β-blocker.
- If given in the ED, continue daily dose and optimize as dictated by HR and BP.

ACE Inhibitor
- Start ACE inhibitor orally in patients with anterior infarction, pulmonary congestion, or LVEF <0.40 if the following are absent: hypotension (SBP < 100 mm Hg or <30 mm Hg below baseline) or known contraindications to this class of medications.

Angiotensin-Receptor Blocker
- Start ARB orally in patients who are intolerant of ACE inhibitors and who have either clinical or radiologic signs of heart failure or LVEF < 0.40.

Pain Meds
- IV morphine sulfate 2-4 mg with increments of 2-8 mg IV at 5-15-min intervals as needed to control pain

Anxiolytics (based on a nursing assessment)
Daily Stool Softener
Laboratory Tests
- Serum biomarkers for cardiac damage,* CBC with platelet count, INR, aPTT, electrolytes, magnesium, BUN, creatinine, glucose, serum lipids

*Do not wait for results before implementing reperfusion strategy.
†Although some trials have used enteric-coated aspirin for initial dosing, more rapid buccal absorption occurs with nonenteric-coated formulations.
ACE, angiotensin-converting enzyme; ARB, angiotensin-receptor blocker; aPTT, activated partial thromboplastin time; BP, blood pressure; bpm, beats per minute; BUN, blood urea nitrogen; CBC, complete blood count; CHF, congestive heart failure; ECG, electrocardiogram; ED, emergency department; h, hours; HR, heart rate; INR, international normalized ratio; IV, intravenous; LVEF, left ventricular ejection fraction; min, minutes; NS, normal saline; NPO, nothing by mouth; NTG, nitroglycerin; SBP, systolic blood pressure; STEMI, ST-elevation myocardial infarction.
Modified from Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction). Circulation 2004;110:588-636.

necessitates prolonged bed rest or minimal activity. It is often discontinued earlier in patients treated with PCI so that the vascular sheaths can be removed. Deep venous thrombosis prophylaxis with subcutaneous LMWH (dosed appropriately for specific agent) or with subcutaneous UFH (7500 U to 12,500 U twice daily) until the patient is completely ambulatory may be useful, but the effectiveness of such a strategy is not well established in the contemporary era of routine aspirin use and early mobilization.

An aPTT measurement and dose adjustment should be made 3 hours after starting intravenous UFH therapy and repeated 6 hours after each dose adjustment and daily thereafter. Rather than abruptly stopping therapy, reducing UFH infusions in a gradual fashion (e.g., by one-half within 6 hours, then discontinuing over the subsequent 12 hours) may decrease the risk of hypercoagulability from heparin rebound. Platelet counts should be monitored daily because of the 3% risk of heparin-induced thrombocytopenia.

β-Blockers

A meta-analysis of trials from the prefibrinolytic era involving over 24,000 patients who received β-blockers in the convalescent phase has shown a reduction in acute ischemic events and

a 23% reduction in long-term mortality.[118] The risk is a 3% incidence of provocation of congestive heart failure or complete heart block and a 2% incidence of cardiogenic shock. β-Blockers are especially beneficial in patients with persistent or recurrent ischemia, evidence for infarct extension, or tachyarrhythmias. Initiation of therapy can be undertaken after 24 to 48 hours of freedom from relative contraindications that include bradycardia and congestive heart failure.

Inhibition of the Renin-Angiotensin-Aldosterone System

An ACE inhibitor should be administered orally during convalescence in patients who tolerate this class of medication. ACE inhibitors should not be used if systolic blood pressure is <100 mm Hg or <30 mm Hg below baseline; if clinically relevant renal failure is present; if there is a history of bilateral stenosis of the renal arteries; or if there is known allergy to ACE inhibitors. The proportional benefit of ACE inhibitor therapy is largest in higher risk subgroups; those patients with previous MI, heart failure, depressed LV ejection fraction (EF), or tachycardia. These patients should be given long-term therapy.[119-121] Survival benefit for the elderly and for low-risk subgroups is equivocal.[120,121] There are no data supporting therapy for longer than 4 to 6 weeks in patients without LV dysfunction. Treatment can be initiated with captopril 6.25 to 12.5 mg three times daily and titrated to 50 mg three times daily. If tolerated, a once daily ACE inhibitor can then be substituted.

An angiotensin receptor blocker should be administered to STEMI patients who are intolerant of ACE inhibitors and with either clinical or radiologic signs of heart failure or EF = 40%.[2] Valsartan (target dose 80 mg twice daily)[122] and candesartan (target dose 32 mg daily)[123] have demonstrated efficacy for this recommendation.

Long-term aldosterone blockade should be prescribed for patients without significant renal dysfunction (creatinine <2.5 mg/dL in men and <2.0 mg/dL in women) or hyperkalemia (potassium <5.0 mEq/L) who are already receiving therapeutic doses of an ACE inhibitor, have an LVEF <40%, and have either symptomatic heart failure or diabetes.[2] The Randomized Aldactone Evaluation Study[124] treated patients with NYHA class III-IV heart failure with either spironolactone (25 to 50 mg daily) or placebo. Over 24 months of follow-up, spironolactone treatment was associated with an 11% absolute and a 24% relative risk reduction in all-cause mortality. The Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS) randomized 6632 patients post-MI with an ejection fraction <40% and heart failure or diabetes to receive eplerenone (target dose 50 mg daily) or placebo in conjunction with routinely indicated cardiac medications.[125] There were significant reductions in overall mortality, cardiovascular mortality, and cardiac hospitalizations.

Glycemic Control

Metabolic modulation with infusions of glucose-insulin-potassium (GIK) was associated with mortality reduction in early trials. These results have not been reproduced in the reperfusion era with fibrinolytic therapy[126] or primary PCI.[127] The results may have been confounded by treatment after reperfusion rather than before reperfusion, later treatment, or treatment in low-risk patients. An excess risk has been reported for those in Killip class II or higher. Therapy with GIK cannot be recommended at the present time. However, compelling evidence for tight glucose control in critically ill patients supports the importance of intensive insulin therapy to achieve a normal blood glucose (80 to 110 mg/dL).[128,129]

Magnesium

Similar to the GIK story, early studies supported a mortality benefit with magnesium administration, but no benefit has been noted in contemporary trials.[31,130] Magnesium can be administered for repletion of documented electrolyte deficits and for life-threatening ventricular arrhythmias such as torsades de pointes.

Calcium Channel Blockers

It is reasonable to give verapamil or diltiazem to patients in whom β-blockers are ineffective or contraindicated (e.g., bronchospastic disease) for relief of ongoing ischemia or control of a rapid ventricular response with atrial fibrillation or flutter after STEMI in the absence of CHF, LV dysfunction, or AV block.[131,132] There are no current data, however, to suggest that these agents decrease cardiac events. Nifedipine (immediate-release) is generally contraindicated in the treatment of STEMI because of reflex sympathetic activation, tachycardia, and hypotension associated with its use.[133]

Hemodynamic Disturbances

Hemodynamic Assessment

Use of a pulmonary artery catheter to measure hemodynamics in patients developing progressive CHF or hypotension may permit the early diagnosis of a preshock state wherein aggressive pharmacologic support can prevent the onset of cardiogenic shock.[134] Before PCI is performed for cardiogenic shock, the interventional cardiologist should insert a pulmonary artery catheter to maximize the hemodynamic status of the patient and to diagnose unrecognized mechanical complications. After reperfusion therapy, the pulmonary artery catheter may be used to guide diuretic, inotropic, and vasopressor agents in hemodynamically unstable patients while the stunned myocardium is recovering. Although there are no randomized clinical trial data testing whether or not hemodynamic monitoring alters clinical outcome in STEMI, one would expect that revascularization of ischemic myocardium would be required for outcomes to be improved.

Complications of pulmonary artery catheterization include ventricular tachyarrhythmias (during manipulation), pulmonary hemorrhage or infarction, and transient right bundle branch block, which can lead to heart block in those with preexisting left bundle branch block. The catheter should not be inserted if the patient responds quickly to other interventions or if treatment is expected to be futile. The catheter should be expeditiously removed when it is no longer needed to monitor therapy or before 4 to 5 days owing to risk of infection.

Hypotension

Hypotension (systolic pressure <90 mm Hg or 30 points below previous mean arterial pressure) can result from hypovolemia, arrhythmias, RV or LV failure, mechanical complications of MI, or superimposed complications such as sepsis or pulmonary embolism. Hypovolemia is a common occurrence and may be due to inadequate intake, diaphoresis and vomiting, overdiuresis, excessive use of vasodilators, or inappropriate reflex peripheral vasodilation. Hemorrhage is an increasingly common problem associated with the use of invasive procedures, fibrinolytics, antiplatelet agents, and anticoagulant agents. Therefore, rapid volume loading is recommended as an initial therapeutic strategy for all patients without clinical evidence for volume overload (Fig. 11–13). Persistent hypotension should be evaluated with an echocardiogram to define the cardiac anatomy and with a hemoglobin measurement. Correction or control of rhythm disturbances or conduction abnormalities often reverses hypotension. In patients with inotropic failure, vasopressors and inotropic agents are

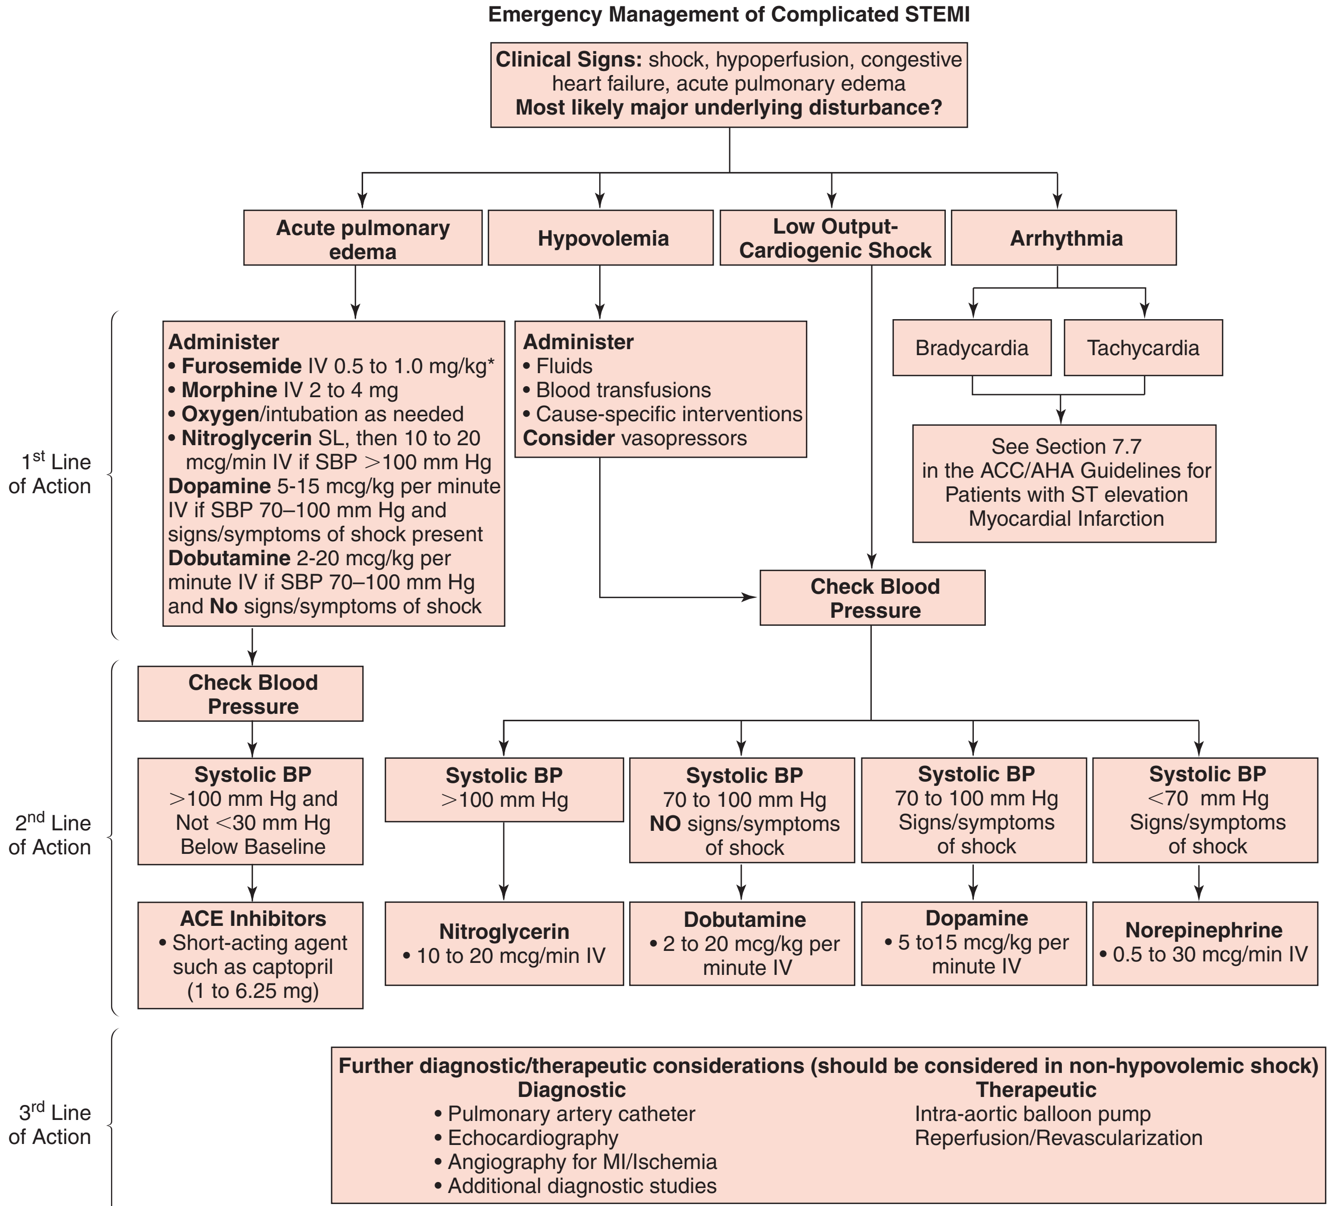

Figure 11–13 Emergency management of complicated ST-elevation myocardial infarction (STEMI). The emergency management of patients with cardiogenic shock, acute pulmonary edema, or both, is shown. *Furosemide <0.5 mg/kg for new onset acute pulmonary edema without hypovolemia; 1 mg/kg for acute or chronic volume overload, renal insufficiency. Nesiritide has not been studied adequately in patients with STEMI. Combinations of medications (e.g., dobutamine and dopamine) may be used. ACE, angiotensin-converting enzyme; BP, blood pressure; IV, intravenous; MI, myocardial infarction; SBP, systolic blood pressure; SL, sublingual. (Adapted from ECC Guidelines: Part 7: The Era of Reperfusion; Section 1: Acute Coronary Syndromes [Acute Myocardial Infarction]. 2000 American Heart Association, Inc. Circulation 2000;102: I-172-203.)

required. Dopamine is the agent of first choice, but norepinephrine may be required for marked hypotension. Once arterial pressure is brought to at least 90 mm Hg, intravenous dobutamine may be given simultaneously in an attempt to reduce the rate of the dopamine infusion. In addition, consideration should be given to initiating intra-aortic balloon pump (IABP) counterpulsation.

Low-Output State

A preshock state of hypoperfusion with normal blood pressure may develop before circulatory collapse and is manifested by cold extremities, cyanosis, oliguria, or decreased mentation.[134] Hospital mortality is high, so these patients should be aggressively diagnosed and treated as if they had cardiogenic shock (see Fig. 11–13). Dobutamine infusion is the initial pharmacologic intervention. IABP therapy may be required to improve coronary artery perfusion pressure if hypotension is present. If the blood pressure permits, afterload reducing agents should be added to decrease cardiac work and pulmonary congestion. Coronary artery revascularization of ischemic myocardium with either PCI or CABG has been shown to decrease mortality in patients with cardiogenic shock and is strongly recommended for suitable candidates.[69,135] Likewise, patients with ventricular septal rupture, papillary muscle rupture, or pericardial tamponade may benefit from emergency surgical repair.

Pulmonary Congestion

LV filling pressures may rise rapidly after acute coronary occlusion. This leads to rapid redistribution of fluid from the intravascular space into the lung interstitium and alveoli. The etiology of pulmonary edema (systolic, diastolic or a mechanical complication [mitral regurgitation or ventricular septal rupture]) should be rapidly assessed with a 2-dimensional echocardiogram with color flow Doppler. Pulmonary congestion increases the risks of death and pulmonary edema and is associated with a 20% to 40% 30-day mortality rate even in the fibrinolytic era.[136,137]

Oxygen supplementation should be administered to maintain the arterial saturation >90%. Management includes the use of agents that acutely reduce preload: nitrates, morphine sulfate, and diuretics (see Fig. 11–13), and avoidance of acute administration of negative inotropic agents (e.g., β-blockers and calcium channel antagonists). A 10-to 20-mcg nitroglycerin bolus should be administered, followed by 10 mcg/min infusion, increased by 5 to 10 mcg/min every 5 to 10 minutes until dyspnea is relieved, the mean arterial pressure is lowered by 10% in normotensive patients or by 30% in hypertensive patients, or until the heart rate increases by more than 10 beats per minute. Loop diuretics (furosemide, torsemide, or bumetanide) should be initiated in low-to-intermediate doses in patients with associated hypervolemia.

Oral ACE inhibitors, preferably a short-acting agent such as captopril, beginning with 1 to 6.25 mg, should be instituted early in normotensive or hypertensive patients. The dosage may be doubled with each subsequent dose, as tolerated, up to 25 to 50 mg every 8 hours, then changed to a long-acting agent. For patients who presented with CHF complicating MI, ramipril administration between days 3 and 10 significantly reduces 30-day mortality.[138] ACE inhibitors are the only adjunctive medication (beyond ASA and reperfusion therapy) shown to reduce 30-day mortality when CHF complicates STEMI, so ACE inhibitors are preferred if blood pressure limits use of vasodilators. Intravenous sodium nitroprusside substantially reduces afterload as well as preload; however, its use has been associated with coronary steal. Digitalis has no role in the management of pulmonary edema that complicates STEMI unless rapid atrial fibrillation is present.

Eplerenone, an aldosterone antagonist, prevented death and recurrent hospitalization in patients 3 to 14 days post-MI with congestive heart failure and LVEF <0.40.[125] Spironolactone improved survival in a population of patients with chronic CHF, which includes those with remote MI[124] and is generic. In contrast to the recommendation to avoid β-blockade during pulmonary edema, β-blockers are strongly recommended before hospital discharge for secondary prevention of cardiac events.[139] The initial dose and titration should be based on clinical heart failure status and LVEF.

Mechanical ventilation may be required. It may be reasonable to insert an IABP when pulmonary congestion is refractory. Analyses from GUSTO IIb[140] and the NRMI registry[80] showed a marked benefit of PCI compared with fibrinolytic therapy for patients with CHF. Coronary angiography and revascularization, based on the anatomy, should be performed when late CHF complicates the hospital course.

Cardiogenic Shock

Fewer than 1% of patients with STEMI present to the hospital in cardiogenic shock, and approximately 7% develop shock after hospital admission. A useful definition of cardiogenic shock is clinical evidence of systemic hypoperfusion with systolic BP <90 mm Hg for at least 30 minutes (or the need for supportive measures to maintain systolic BP >90 mm Hg), cardiac index <2.2 liters per minute per square meter, and PCWP at least 15 mm Hg.

Cardiogenic shock is caused by extensive LV dysfunction in 75% of patients. Other causes include acute severe mitral regurgitation, ventricular septal rupture, subacute free wall rupture with tamponade, and RV infarction. Aortic dissection and hemorrhagic shock may mimic cardiogenic shock and need to be excluded in the differential diagnosis. Echocardiography with color flow Doppler should be used to define the etiology of shock.

Patients with cardiogenic shock secondary to myocardial ischemia and infarction should be resuscitated as quickly as possible. Restoration of sinus rhythm, adequate ventilation, correction of acid-base abnormalities, and inotropic and vasopressor therapy to support tissue perfusion are important interventions. They should be treated with reperfusion therapy, unless further care is deemed futile (Fig. 11–14). However, reperfusion rates with fibrinolytic therapy are reduced in cardiogenic shock because of low cardiac output, and it is not clear that survival rates are improved. In contrast, more than 20 observational studies have suggested that reperfusion with PCI or CABG improves survival rates.[137]

Two randomized trials have been performed. The SHOCK trial[69,135] randomized 302 patients to either emergency revascularization or initial medical stabilization. The 30-day mortality rate for emergency revascularization patients was 46.7% versus 56.0% for initial medical stabilization patients ($P = 0.11$). However, the mortality rate was significantly lower

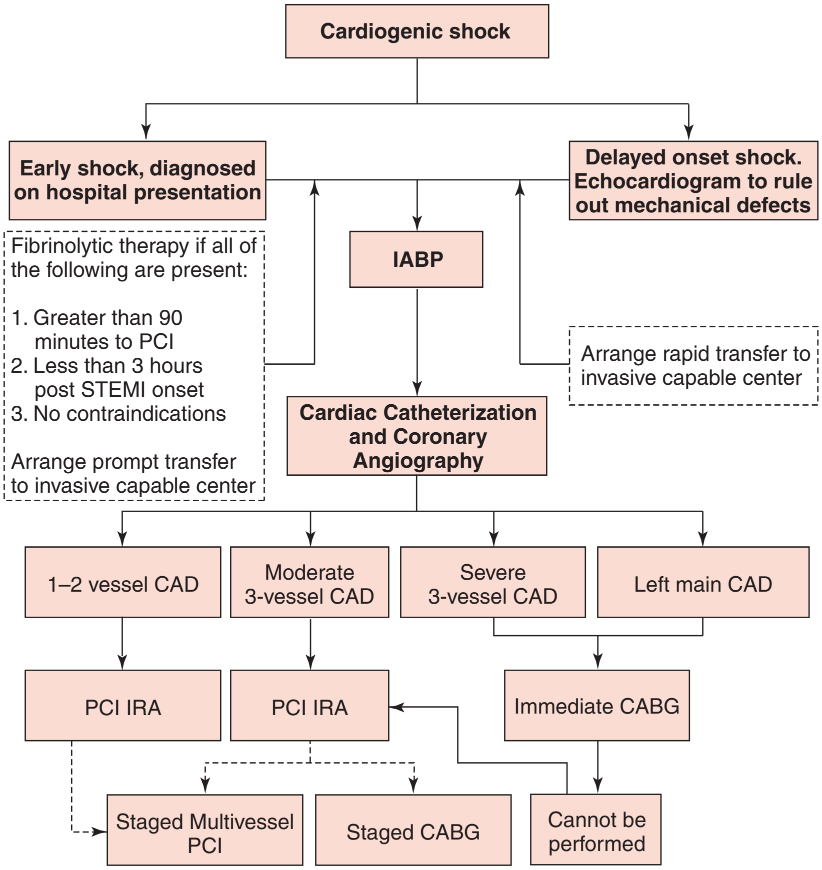

Figure 11–14 Recommendations for initial reperfusion therapy when cardiogenic shock complicates STEMI. Early mechanical revascularization with PCI/CABG is a class I recommendation for candidates <75 years of age with ST elevation or LBBB who develop shock <36 hours from STEMI and in whom revascularization can be performed within 18 hours of shock, and a class IIa recommendation for patients ≥75 years of age with the same criteria. Eighty-five percent of shock cases are diagnosed after initial therapy for STEMI, but most patients develop shock within 24 hours. An IABP is recommended when shock is not quickly reversed with pharmacologic therapy, as a stabilizing measure for patients who are candidates for further invasive care. *Dashed lines* indicate that the procedure should be performed in patients with specific indications only. CABG, coronary artery bypass graft surgery; CAD, coronary artery disease; IABP, intra-aortic balloon pump; IRA, infarct-related artery; LBBB, left bundle branch block; PCI, percutaneous coronary intervention; STEMI, ST-elevation myocardial infarction. (Adapted from Hochman JS: Cardiogenic shock complicating acute myocardial infarction: Expanding the paradigm. Circulation 2003;107: 2998-3002, with permission.)

in the emergency revascularization group at 6 months (50.3% versus 63.1%, $P < 0.03$) and 12 months (53.3 % versus 66.4, $P < 0.03$). Similarly, the (S)MASH study ([Swiss] Multicenter Trial of Angioplasty for Shock) randomly assigned 55 refractory shock patients to either PCI or conventional care.[141] As in SHOCK, the mortality rate in the PCI group was 9 absolute percentage points lower at 30 days (69% versus 78%) than the conventional therapy group, but did not reach statistical significance because of sample size. The results of the SHOCK trial and registry and the SMASH trial have proved that appropriate candidates with cardiogenic shock complicating acute MI should be referred for coronary angiography and emergency revascularization unless contraindications exist. These include life-shortening illnesses, previously defined coronary anatomy unsuitable for revascularization, anoxic brain damage, and patients for whom further therapy appears to be futile.

Triple-vessel disease (60%) and left main disease (20%) are often present when shock complicates STEMI. Among the emergency revascularization groups in the SHOCK trial, 60% received PCI and 40% had CABG. The 30-day mortality rate was 45% and 42%, respectively, despite more severe CAD and twice the frequency of diabetes in patients treated with CABG. This was in contrast to the 69% in-hospital mortality rate reported for those with three-vessel CAD who underwent PCI. Although CABG will be an option for some patients, most will be treated with PCI of the infarct artery. Surviving patients with multivessel disease can subsequently be considered for additional PCI or CABG to achieve more complete revascularization.

The only subgroup of patients that did not receive a treatment benefit in the SHOCK trial was the 56 patients who were 75 years or older. However, analysis of the 44 elderly patients in the SHOCK Trial registry[142] selected for early revascularization showed a significantly lower mortality rate than that of the 233 patients who did not undergo revascularization (48% versus 81%; $P = 0.0002$). Other reports[143,144] also support the use of primary PCI in carefully selected older patients with cardiogenic shock complicating MI, so age alone should not be an exclusion criterion for selecting patients for cardiac catheterization.

Fibrinolytic therapy should be administered to those who are not candidates for early revascularization and who do not have contraindications for lytic therapy. Patients who present to hospitals without revascularization capability should be transferred to a hospital with revascularization capability. IABP placement prior to transport may help stabilize the patient. If the patient presents in shock within 3 to 6 hours of MI onset and delays in transport and intervention are anticipated, both fibrinolytic therapy and IABP counterpulsation may be initiated.[145]

Right Ventricular Infarction

RV ischemia can be demonstrated in up to one half of patients with inferior STEMI, although only 10% to 15% show the

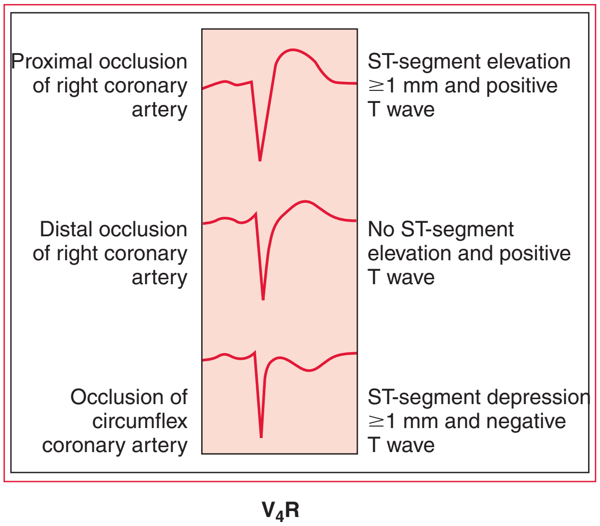
classic hemodynamic abnormalities of clinically significant RV infarction.[83,146] These patients represent a high-risk subgroup of patients with a 25% to 30% mortality rate.[147] In the SHOCK trial registry, patients with predominant RV infarction and cardiogenic shock had a mortality rate similar to patients with LV shock (53% versus 61%).[148]

The right coronary artery usually supplies most of the RV myocardium. Occlusion of this artery proximal to the RV branches will lead to RV ischemia. Most survivors demonstrate a return of normal RV function over a period of weeks to months, suggesting that RV stunning, rather than irreversible necrosis, has occurred. Pathophysiologic reasons for this phenomenon include lower oxygen demand because of lower myocardial mass than in the LV,[149] coronary perfusion during both diastole and systole,[150] and more favorable oxygen supply than in the LV because of more extensive collateral supply.[151]

The extent of RV dysfunction, the restraining effect of the surrounding pericardium, and interventricular dependence related to the shared interventricular septum determine the hemodynamic effect of RV ischemia. The ischemic RV dilates, increasing intrapericardial pressure because of the restraining forces of the pericardium. Consequently, there is a reduction in RV systolic pressure and output, decreased LV preload, a reduction in LV end-diastolic dimension and stroke volume, and a shifting of the interventricular septum toward the LV.[152] The pressure gradient between the right and left atria becomes an important driving force for pulmonary perfusion. Factors that reduce preload (volume depletion, diuretics, morphine, nitrates) or diminish augmented right atrial contraction (atrial infarction, loss of AV synchrony, atrial fibrillation), or factors that increase RV afterload (LV dysfunction), can have profound adverse hemodynamic effects.[153,154] Paradoxic interventricular septal motion that bulges in piston-like fashion into the RV, is important in generating systolic force, which improves pulmonary perfusion.[155] Concomitant septal infarction may result in the loss of this compensatory mechanism.

All patients with inferior STEMI should be evaluated for possible RV ischemia/infarction. The clinical triad of hypotension, clear lung fields, and elevated jugular venous pressure in the setting of IMI is specific, but has a sensitivity of <25%.[156] Distended neck veins alone or the presence of the Kussmaul sign (distention of the jugular vein on inspiration) are both sensitive and specific,[157] unless the patient is volume depleted. All patients with inferior STEMI should be screened for RVMI with right-sided ECG recordings at the time of admission (Fig. 11–15). Demonstration of 1-mm ST-segment elevation in the lead V_1 and in the right precordial lead V_4R is the most predictive electrocardiographic finding in patients with RV ischemia[158] but may resolve within 10 hours of onset of symptoms.[159] Echocardiography can show RV dilation and asynergy or abnormal interventricular and interatrial septal motion. Right-to-left shunting through a patent foramen ovale should be suspected when persistent hypoxia is not responsive to supplemental oxygen and can be documented with the color flow Doppler examination.[160] Pulmonary artery catheterization may be helpful in diagnosing RV ischemia/infarction. A right atrial pressure of 10 mm Hg or greater and >80% of pulmonary wedge pressure is a relatively sensitive and specific finding.

Successful reperfusion therapy can prevent or reverse the hemodynamic complications of RVMI. PCI is particularly useful in patients with hypotension or shock because RV ischemic dysfunction resolves quickly with successful reperfusion. The medical treatment of patients with RV ischemic dysfunction is different than, and often diametrically opposed to, management of LV dysfunction. The first goal is to maintain RV preload. Nitrates, morphine, and diuretics are routinely used in LVMI, but should be avoided in RVMI because they may reduce RV preload, cardiac output, and blood pressure. Volume loading with normal saline can improve cardiac output and blood pressure, but should not be excessive because RV dilatation shifts the interventricular septum into the LV, decreasing LV output.[161] The second goal is to provide inotropic support for the ischemic right ventricle with dobutamine hydrochloride. The third goal is to maintain AV synchrony. High-degree AV block may occur in as many as one half of these patients.[162] Atrioventricular sequential pacing may restore normal blood pressure when ventricular pacing alone has been unsuccessful.[163] Atrial fibrillation may occur in up to one third of patients and should be treated with cardioversion if hemodynamic compromise is present. The



Clinical findings:
Shock with clear lungs, elevated JVP, Kussmaul sign

Hemodynamics:
Increased RA pressure (y descent)
Square root sign in RV tracing

ECG:
ST elevation in R sided leads

Echo:
Depressed RV function

Management:
Maintain RV preload
Lower RV afterload (PA—PCW)
Restore AV Synchrony
Inotropic support
Reperfusion

Figure 11–15

fourth goal is to decrease RV afterload in the setting of LV failure. This can be accomplished with afterload-reducing agents or intra-aortic balloon counterpulsation.

Mechanical Complications

Mitral Regurgitation

Patients with mild mitral regurgitation after STEMI have a worse prognosis than patients without mitral regurgitation.[164] Severe mitral regurgitation may be due to either posterior papillary muscle infarction, ischemia, or marked LV dilatation secondary to extensive infarction and remodeling (Table 11–7). Initial management should include afterload reduction and possible IABP. If the mitral regurgitation does not improve over several days or if surgery is required because of critical coronary anatomy or ongoing ischemia, a transesophageal echocardiogram should be performed to help determine whether valve replacement or annuloplasty is indicated. Mitral valve surgery, usually annuloplasty, should be performed at the same time as CABG for patients with moderate ischemic mitral regurgitation.[165]

The presence of pulmonary edema or cardiogenic shock suggests the possibility of acute papillary muscle rupture. If acute papillary muscle rupture is confirmed by echocardiography, urgent surgery should be pursued because delay increases the risk of further myocardial injury, other organ injury, and death.[166] These patients should be stabilized with afterload reduction, inotropic support, and an IABP, and should undergo coronary angiography before surgery. In the SHOCK Trial Registry,[167] 8% of patients with shock presented with severe MR and had an overall hospital mortality rate of 55%. Mortality with medical treatment was 71% compared with 40% treated with surgery.

Table 11–7 Characteristics of Ventricular Septal Rupture, Rupture of the Ventricular Free Wall, and Papillary-Muscle Rupture

Characteristic	Ventricular Septal Rupture	Rupture of Ventricular Free Wall	Papillary-Muscle Rupture
Incidence	1-3% without reperfusion therapy, 0.2-0.34% with fibrinolytic therapy, 3.9% among patients with cardiogenic shock	0.8-6.2%. Fibrinolytic therapy does not reduce risk; primary PTCA seems to reduce risk	About 1% (posteromedial more frequent than anterolateral papillary muscle)
Time course	Bimodal peak; within 24 hours and 3-5 days; range 1-14 days	Bimodal peak; within 24 hours and 3-5 days; range 1-14 days	Bimodal peak; within 24 hours and 3-5 days; range 1-14 days
Clinical manifestations	Chest pain, shortness of breath, hypotension	Anginal, pleuritic, or pericardial chest pain, syncope, hypotension, arrhythmia, nausea, restlessness, hypotension, sudden death	Abrupt onset of shortness of breath and pulmonary edema; hypotension
Physical findings	Harsh holosystolic murmur, thrill (+), S_3, accentuated 2nd heart sound, pulmonary edema, RV and LV failure, cardiogenic shock	Jugulovenous distention (29% of patients), pulsus paradoxus (47%), electromechanical dissociation, cardiogenic shock	A soft murmur in some cases, no thrill, varying signs of RV overload, severe pulmonary edema, cardiogenic shock
Echocardiographic findings	Ventricular septal rupture, left-to-right shunt on color flow Doppler echocardiography through the ventricular septum, pattern of RV overload	>5 mm pericardial effusion not visualized in all cases, layered, high-acoustic echoes within the pericardium (blood clot), direct visualization of tear, signs of tamponade	Hyper-contractile LV, torn papillary muscle or chordae tendineae, flail leaflet, severe mitral regurgitation on color flow Doppler echocardiography
Right-heart catheterization	Increase in oxygen saturation from the RA to RV, large V waves*	Ventriculography insensitive, classic signs of tamponade not always present (equalization of diastolic pressures among the cardiac chambers)	No increase in oxygen saturation from the RA to RV, large V waves*, very high pulmonary capillary wedge pressures

*Large V waves are from the pulmonary capillary wedge pressure.
LV, left ventricle; PTCA, percutaneous transluminal coronary angioplasty; RA, right atrium; RV, right ventricle.
Modified from Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction). Circulation 2004;110:588-636.

Ventricular Septal Rupture

The diagnosis of ventricular septal rupture can be confirmed by color flow Doppler echocardiography or by a step-up in oxygen saturation from the right atrium to the pulmonary artery (see Table 11–7). Similar to acute severe mitral regurgitation, management includes inotropic and vasodilator therapy, intra-aortic balloon counterpulsation, and immediate surgical repair. The usual operation involves excision of all necrotic tissue, patch repair of the septal rupture, and CABG. In the GUSTO-1 trial,[168] the mortality rates for surgical or medically treated patients with ventricular septal rupture were 47% and 94%, respectively. In patients with cardiogenic shock enrolled in the SHOCK registry,[169] mortality rates for surgical or medically treated patients were 81% and 96%, respectively. Therefore, if possible, hemodynamically stable patients should undergo emergency surgery before the onset of shock.

Left Ventricular Free Wall Rupture

Cardiac rupture occurs in 1% to 6% of patients and accounts for 15% of in-hospital mortality (see Table 11–7).[170] Early reperfusion and the presence of collateral circulation decrease the risk of free wall rupture. Risk factors include advanced age, female gender, first infarction, large infarction, and delivery of fibrinolytic therapy more than 14 hours after onset of symptoms.[170,171] Many patients die rapidly with irreversible electromechanical dissociation, but others develop hypotension and pericardial tamponade. The diagnosis of tamponade or pseudoaneurysm can be made quickly by echocardiography. Rapid volume administration and transfer to the operating room without cardiac catheterization for emergency surgery is recommended. The surgical mortality rate is approximately 60%.[172,173]

Left Ventricular Aneurysm

Ventricular aneurysm formation usually occurs in association with left anterior descending artery occlusion and a wide area of infarction. Clinical complications include angina pectoris, CHF, thromboembolism, and ventricular arrhythmias. Successful reperfusion therapy decreases the risk of aneurysm formation. Surgery is rarely required for control of heart failure or intractable ventricular arrhythmias unresponsive to conventional therapy. Surgical techniques include plication, excision with linear repair, and ventricular reconstruction using endoventricular patches to maintain better physiologic function.[174] Left ventricular size and function determine prognosis. Surgical mortality is 3% to 7%.

Mechanical Support Devices

IABP counterpulsation improves diastolic coronary blood flow and reduces myocardial work by afterload reduction. It should be used in patients with hypotension (systolic blood pressure <90 mm Hg or 30 points below previous mean arterial pressure) who do not respond to other interventions, low output syndrome, or cardiogenic shock. It also is useful for patients with recurrent ischemic-type chest discomfort and signs of hemodynamic instability, poor LV function, or a large area of myocardium at risk to stabilize them for cardiac catheterization and possible revascularization. Intra-aortic balloon counterpulsation may also be a reasonable intervention in the management of refractory polymorphic ventricular tachycardia or refractory congestive heart failure. Other support devices that are rarely used because of the comorbidities in these patients are left ventricular assist devices and extracorporeal membrane oxygenation. Survivors may become elective cardiac transplantation candidates.

Arrhythmias

Bradyarrhythmias

Bradyarrhythmias may be due to overstimulation of vagal afferent receptors and resulting cholinergic stimulation or to ischemic injury of conducting tissue. Sinus bradycardia is frequent, especially in the first hours of inferior STEMI, with reperfusion of the right coronary artery (Bezold-Jarisch reflex), or after the use of β-blocker or calcium antagonist medications (see Chapter 5). Intraventricular conduction delay has been reported in 10% to 20% of patients and heart block may develop in 6% to 14% of patients (Table 11–8). Both are associated with an increased mortality risk because they are generally related to a larger ischemia/infarct zone.[22]

Symptomatic Mobitz I AV block, symptomatic sinus bradycardia, sinus pauses >3 seconds, and sinus bradycardia with a heart rate <40 beats per minute associated with hypotension or signs of systemic hemodynamic compromise should be treated with an intravenous bolus of atropine 0.6 to 1.0 mg. Isoproterenol and aminophylline are not recommended because they are arrhythmogenic and increase myocardial oxygen demand. Glucagon has been used to treat bradycardia caused by toxic doses of β-blockers and calcium channel blockers.[175] If bradycardia is persistent, and maximal (2 mg) doses of atropine have been used, transcutaneous or transvenous temporary pacing should be instituted. When there is infranodal AV block, atropine may increase the sinus rate without affecting infranodal conduction, and so the effective ratio of conduction may decrease, and ventricular rate may decrease. Therefore, temporary pacing should be used instead of pharmacologic therapy.

Ventricular asystole may be caused either by failure of the sinus node to generate a cardiac impulse or by the development of complete heart block, with concurrent failure of the usual underlying atrial, junctional, or ventricular escape mechanisms. Treatment of the acute event requires prompt institution of chest compressions, atropine, vasopressin (40 IU), epinephrine, and transcutaneous pacing. It is important to address the underlying cause and discontinue medications that suppress electrical activity.

The decision to implant a permanent pacemaker for sinus node dysfunction or Mobitz I second-degree AV block should be delayed several days because the conduction abnormality usually resolves and does not affect long-term prognosis.[176] Permanent ventricular pacing is indicated for persistent second-degree or third-degree AV block or transient second- or third-degree infranodal AV block associated with bilateral bundle branch block. Patients who have permanent atrial fibrillation or flutter should receive a ventricular-pacing system. Patients who are in sinus rhythm should receive a permanent dual chamber pacemaker. Patients with heart failure may be candidates for resynchronization therapy with

Table 11–8 Features of Atrioventricular Conduction Disturbances in Acute Myocardial Infarction

	Location of AV Conduction Disturbance	
Feature	Proximal	Distal
Site of block	Intranodal	Infranodal
Site of infarction	Inferoposterior	Anteroseptal
Compromised arterial supply	RCA (90%), LCx (10%)	Septal perforators of LAD
Pathogenesis	Ischemia, necrosis, hydropic cell swelling, excess parasympathetic activity	Ischemia, necrosis, hydropic cell swelling
Predominant type of AV nodal block	First degree (PR > 200 msec) Mobitz type I second degree	Mobitz type II second degree Third degree
Common promontory features of third-degree AV block	First-second degree Mobitz type I pattern	
Features of escape following third-degree block		
• Location	• Proximal conduction system (His bundle)	• Distal conduction system (bundle branches)
• QRS width	• <0.12 sec*	• >0.12 sec*
• Rate	• 45-60 per min but may be as low as 30 per min	• Often <30 per min
• Stability of escape rhythm	• Rate usually stable; asystole uncommon	• Rate often unstable with moderate-to-high risk of ventricular asystole
Duration of high-grade AV block	Usually transient (2-3 days)	Usually transient, but some form of AV conduction disturbances and/or intraventricular defect may persist
Associated mortality rate	Low unless associated with hypotension and/or congestive heart failure	High because of extensive infarction associated with power failure or ventricular arrhythmias
Pacemaker therapy		
• Temporary	• Rarely required; may be considered for bradycardia associated with left ventricular power failure, syncope, or angina	• Indicated in patients with anteroseptal infarction and acute bifascicular block
• Permanent	• Almost never indicated; because conduction defect is usually transient	• Indicated for patients with high-grade AV block with block in His-Purkinje systems and those with transient advanced AV block and associated bundle branch block

*Some studies suggest that a wide QRS escape rhythm (>0.12 sec) after high-grade AV block in inferior infarction is associated with a worse prognosis.
AV, atrioventricular; RCA, right coronary artery; LCx, left circumflex artery; LAD, left anterior descending artery.
Modified from Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction). Circulation 2004;110:588-636.

biventricular pacing. Patients who have severe left ventricular dysfunction and an indication for permanent pacing should be evaluated for implantable cardioverter-defibrillator (ICD) indications.

Supraventricular Arrhythmia

Atrial fibrillation can occur in as many as 20% of patients in high-risk subgroups. Precipitating factors for atrial fibrillation and atrial flutter include excessive sympathetic stimulation, atrial stretch due to LV or RV dysfunction, atrial infarction due to circumflex or right coronary lesions, pericarditis, hypokalemia, underlying chronic lung disease, and hypoxia. Atrial fibrillation predicts a worse in-hospital and long-term outcome.[177,178] Systemic embolization is more frequent in patients with paroxysmal atrial fibrillation (1.7%) compared with those without (0.6%), with one half of embolic events occurring on the first day of hospitalization and more than 90% occurring by the fourth day.[179] Patients with atrial fibrillation or atrial flutter need to be considered for cardioversion, rate control, and anticoagulation therapy.

Synchronized cardioversion should be performed if the patient has persistent ischemic pain or is unstable because of tachycardia, hypotension, or heart failure. Brief general anesthesia or conscious sedation should precede an initial monophasic shock of 200 J for atrial fibrillation and 50 J for

atrial flutter. Successive shocks, if required, should increase in increments of 100 J. The interval between two consecutive shocks should not be <1 minute to avoid myocardial damage.[180]

Rate control can be achieved with intravenous β-blocker therapy, intravenous diltiazem (20 mg [0.25 mg/kg]) over two minutes followed by an infusion of 10 mg/hour, or intravenous verapamil (2.5 to 10 mg over 2 minutes; may repeat after 15 to 30 minutes). If these agents are contraindicated because of CHF or severe pulmonary disease, amiodarone is effective and well tolerated. If anticoagulation is required, either UFH or LMWH may be used.

Reentrant paroxysmal supraventricular tachycardia, because of its rapid rate, should be treated with the following in sequence: carotid sinus massage, intravenous adenosine (6 mg × 1 over 1 to 2 seconds; if no response, 12 mg over 1 to 2 seconds), intravenous β-adrenergic blockade, intravenous diltiazem, and intravenous digoxin. Both paroxysmal supraventricular tachycardia and atrial flutter can be terminated with atrial pacing.

Ventricular Arrhythmias

The mechanisms for ventricular tachyarrhythmias include loss of transmembrane resting potential, reentrant mechanisms due to dispersion of refractoriness in the border zones between infarcted and nonischemic tissues, and the development of foci of enhanced automaticity. Reperfusion arrhythmias appear to involve washout of toxic metabolites and of various ions such as lactate and potassium. Important contributing factors include heightened adrenergic tone, hypokalemia, hypomagnesemia, intracellular hypercalcemia, acidosis, free fatty acid production from lipolysis, and free radical production from reperfusion of ischemic myocardium.

Treatment of isolated ventricular premature beats, couplets, nonsustained ventricular tachycardia (VT), and accelerated idioventricular rhythm is not indicated. Electrolytes and pH should be normalized. The majority of episodes of VT and VF after STEMI occur within the first 48 hours.[181] Sustained VT or VF that occurs more than 48 hours after STEMI may denote an arrhythmic substrate that deserves further evaluation by electrophysiology testing.

Immediate cardioversion is generally not needed for sustained VT rates <150 beats per minute unless hemodynamic compromise is present. Sustained monomorphic VT not associated with angina, pulmonary edema, or hypotension (blood pressure <90 mm Hg) should be treated with amiodarone 150 mg infused over 10 minutes (alternative dose 5 mg/kg) and repeated 150 mg every 10 to 15 minutes as needed. An alternative infusion is 360 mg over 6 hours (1 mg/min), then 540 mg over the next 18 hours (0.5 mg/min). The total cumulative dose, including additional doses given during cardiac arrest, must not exceed 2.2 g over 24 hours. A procainamide bolus and infusion is another option. Synchronized electrical cardioversion starting at monophasic energies of 50 J can also be performed. Sustained VT (more than 30 seconds or causing hemodynamic collapse) should be treated immediately with a synchronized electrical shock of 100 J. Increasing energies may be used if the initial shock is not successful.

Sustained polymorphic VT should be considered in a similar fashion to VF and managed with an unsynchronized electrical shock starting at 200 J. Uncontrolled ischemia and increased sympathetic tone are best treated by intravenous β-blockade, IABP, or emergency revascularization. Intravenous magnesium may be needed to increase serum magnesium to >2.0 mg/dL, and serum potassium should be >4.0 mEq/dL. If the patient has a heart rate of <60 beats per minute or a long QTc interval, temporary pacing at a higher rate may be instituted.

Primary VF is more prevalent in patients aged >75 years[182] and the incidence is highest (3% to 5%) in the first 4 hours of STEMI.[181] Current early therapeutic interventions appear to have decreased the incidence of primary VF[183] and the case fatality rate appears to be declining.[184] Primary VF increases hospital mortality but not long-term prognosis in survivors.[185] Current data do not support prophylactic antiarrhythmic therapy.[186,187] However, intravenous β-blockade and normalization of potassium and magnesium levels may decrease the risk of primary VF.[188] Ventricular fibrillation or pulseless VT should be treated with an unsynchronized electrical shock with an initial monophasic shock energy of 200 J, progressing to 300 J, and 360 J, if necessary. For patients with VF not easily converted by defibrillation, vasopressin 40 U intravenous push may be substituted for epinephrine 1 mg.[189] VF or pulseless VT that is refractory to electrical shock can be treated with amiodarone (300 mg or 5 mg/kg, IV bolus) followed by a repeat unsynchronized electrical shock.

An ICD is indicated for patients with VF or sustained VT more than 48 hours after STEMI (Fig. 11–16).[190-192] Prophylactic ICD implantation is also indicated for patients with a reduced left ventricular ejection fraction at least 1 month after STEMI.[193-195,195a]

Recurrent Chest Pain

Recurrent Ischemia/Infarction

Chest pain similar to the initial ischemic-type chest discomfort can occur at rest or with limited activity during hospitalization. This may or may not be associated with reelevation of the CK-MB, ST segment depression or elevation, or pseudonormalization of inverted T waves. Reinfarction occurs in 4% to 5% of patients after fibrinolytic therapy and aspirin. Diagnosis should be based on recurrence of severe ischemic-type chest discomfort that lasts at least 30 minutes, recurrent ST-segment elevation, and reelevation of CK-MB to more than the upper limit of normal or increased by at least 50% over the previous value. Complications include severe CHF, cardiogenic shock, arrhythmias, cardiac arrest, and death.[86,196] Recurrent MI after fibrinolysis increases the risk of mortality by up to 2 years, but most of the deaths occur in the hospital with little additional risk of death occurring between the time of the index hospitalization and 2 years.[197]

Nitrate and β-blocker therapy should be optimized, and therapeutic anticoagulation should be achieved. Secondary causes of recurrent ischemia (poorly controlled heart failure, anemia, and arrhythmias) should be corrected. Coronary arteriography can clarify the cause of chest discomfort and facilitate PCI or CABG if indicated. Readministration of fibrinolytic therapy may be reasonable for patients who

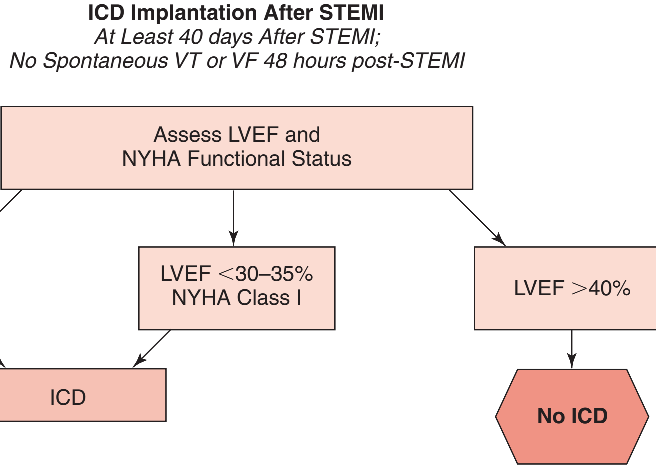

Figure 11–16 Algorithm for assessment of need for implantation of a cardioverter/defibrillator. The appropriate management is selected based upon measurement of left ventricular ejection fraction and assessment of the NYHA functional class. Patients with depressed left ventricular function at least 40 days post-STEMI are referred for insertion of an implantable cardioverter/defibrillator (ICD) if the LVEF is <30–40% and they are in NYHA class II-III or if the LVEF is <30–35% and they are in NYHA class I functional status. Patients with preserved left ventricular function (LVEF >40%) do not receive an ICD regardless of NYHA functional class. All patients are treated with medical therapy post-STEMI. (Adapted from data contained in Zipes DP, Camm AJ, et al. ACC/AHA/ESC 2006 guidelines for management of patients with ventricular arrhythmias and the prevention of sudden cardiac death; a report of the American College of Cardiology/American Heart Association Task Force and the European Society of Cardiology Committee for Practice Guidelines [Writing Committee to Develop Guidelines for Management of Patients with Ventricular Arrhythmias and the Prevention of Sudden Cardiac Death]. J Am Coll Cardiol 2006;48:1064-1108).

are not considered candidates for revascularization or for whom coronary angiography and PCI cannot be rapidly implemented.

Pericarditis

Pericarditis can complicate transmural STEMI and is associated with larger infarcts, a lower EF, and a higher incidence of CHF.[198,199] Pericarditis may appear up to several weeks after STEMI and can be confused with recurrent ischemia. However, pericardial pain is usually pleuritic and/or positional and radiates to the left shoulder, scapula, or trapezius muscle. Detection of a 3-component rub is diagnostic of pericarditis. The electrocardiogram may demonstrate J-point elevation with concave upward ST-segment elevation and PR depression. A small pericardial effusion on an echocardiogram is not diagnostic of pericarditis. The incidence of pericarditis has decreased in the reperfusion era, and the Dressler syndrome (post-MI syndrome), an autoimmune-type carditis, has essentially disappeared.[200]

Aspirin (160 to 325 mg daily) is the treatment of choice, but high doses (650 mg every 4 to 6 hours) may be required.[201] Colchicine 0.6 mg orally every 12 hours or acetaminophen 500 mg orally every 12 hours can be used if episodes are not controlled with aspirin.[202] Nonsteroidal anti-inflammatory drugs may be considered for pain relief, but they should not be used for extended periods because they can decrease aspirin efficacy and increase the risk of myocardial scar thinning and infarct expansion. Corticosteroids should not be used except as a last resort because they have been associated with scar thinning and myocardial rupture.[203] Antithrombotic therapy can usually be continued safely but requires added vigilance for the detection of enlarging pericardial effusion or signs of hemodynamic instability.

Other Complications

Ischemic Stroke

Acute stroke complicates 0.75% to 1.2% of STEMIs and has a >40% mortality rate.[204] Earlier stroke, hypertension, old age, decreased EF, multiple ulcerated plaques, and AF are the major risk factors for embolic stroke post-STEMI.[205] Embolic stroke post-STEMI originates from LV thrombus or from the left atrium in the setting of atrial fibrillation and occurs even in patients treated with fibrinolysis. Most ischemic cerebral infarctions after fibrinolytic therapy occur more than 48 hours after treatment.[206] The highest risk period is the first 28 days post-STEMI,[207] but risk is elevated for at least up to 1 year. Compared with ICH, patients with ischemic cerebral infarction present more commonly with focal neurologic deficits and less commonly with a depressed level of consciousness. Headache, vomiting, and coma are uncommon.[208]

An algorithm for evaluation and antithrombotic therapy for ischemic stroke is shown in Figure 11–17. Ischemic cerebral dysfunction may be presumed with the sudden onset of a focal neurologic deficit, an initial CT scan negative for blood or mass effect, and the absence of a severe metabolic disorder, seizures, autoimmune disease, or cancer. Neurologic consultation is recommended to assist with planning the neurovascular evaluation and management issues. The location and nature of the ischemic brain lesion should be defined with repeat CT scan or MRI scan. Vascular lesions should be evaluated with noninvasive techniques, such as carotid

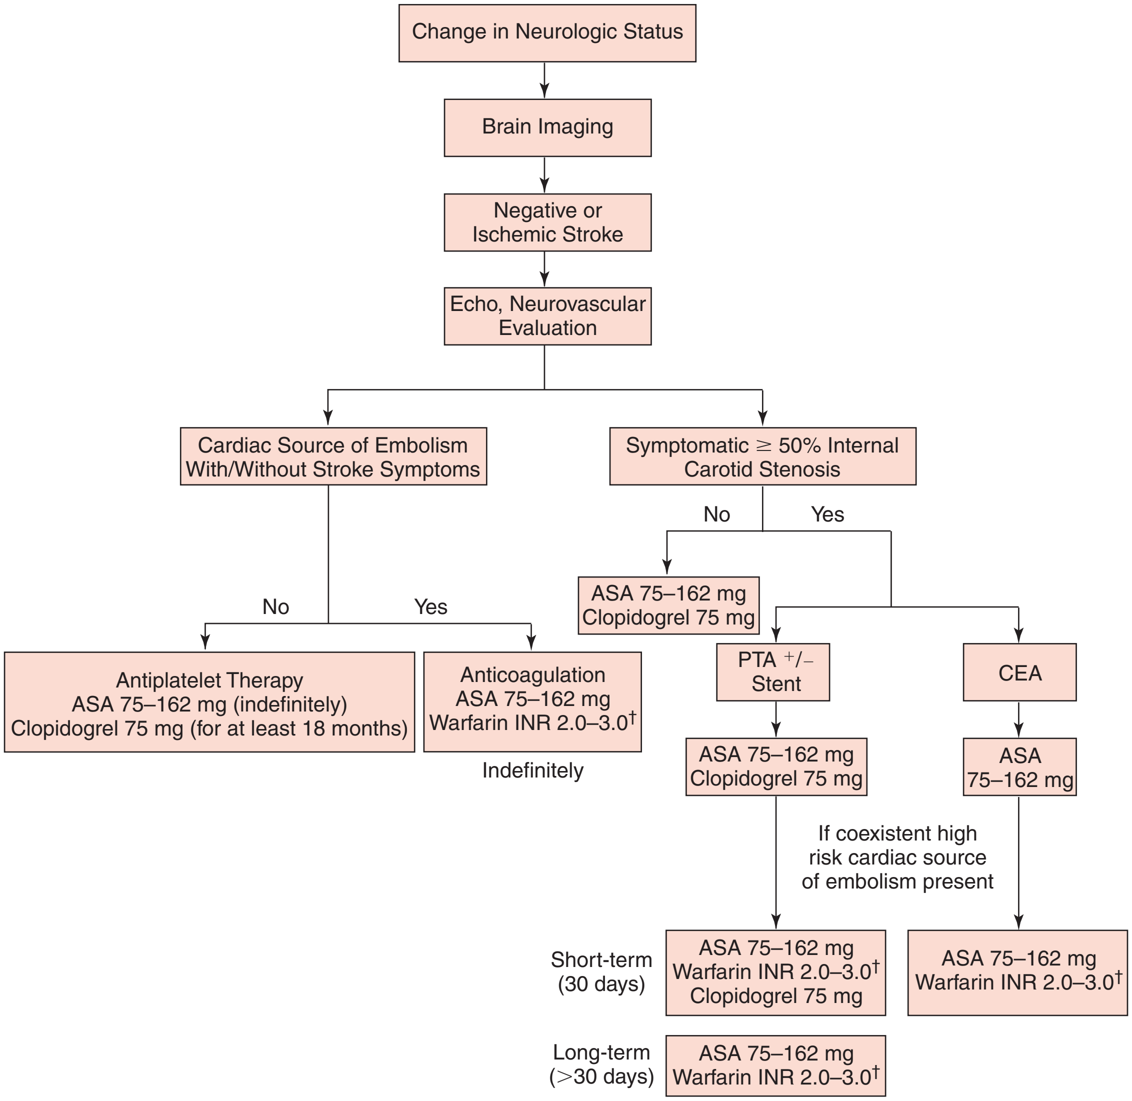

Figure 11–17 Algorithm for post-reperfusion ischemic stroke treatment. Daily doses of antithrombotic therapy are shown in the algorithm. *An INR of 2.0 to 3.0 is acceptable with tight control, but the lower end of the range is preferable. The combination of antiplatelet therapy and warfarin may be considered in patients <75 years of age, with low bleeding risk, and who can be monitored reliably. ASA, aspirin; CEA, carotid endarterectomy; INR, international normalized ratio; PTA, percutaneous transluminal angioplasty (carotid). (Adapted from Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee to revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction]. Circulation 2004;110:588-636, with permission.)

duplex sonography, transcranial Doppler, magnetic resonance angiography, CT angiography, or transesophageal echocardiography. For carotid territory symptoms and signs, evidence for a >50% stenosis should be sought.

Both aspirin[34] and clopidogrel[209] reduce the occurrence of ischemic stroke. Patients with cardiogenic sources of embolism, such as AF, LV mural thrombi or akinetic segment of the left ventricular myocardium, should receive moderate intensity (INR 2-3) warfarin anticoagulation in combination with aspirin. In general, STEMI patients with LV mural thrombus should receive 3 months of warfarin therapy. Ischemic stroke patients with preexisting or persistent AF require lifelong warfarin therapy. A significant carotid artery stenosis may require treatment either with carotid stenting or carotid endarterectomy.

Deep Venous Thrombosis and Pulmonary Embolism

Deep venous thrombosis and pulmonary embolism occur infrequently. Low-dose heparin prophylaxis, preferably with a LMWH, should be given to patients with CHF who are unable to ambulate or who are considered at high risk for deep venous thrombosis. Most patients with deep venous thrombosis or pulmonary embolism should be anticoagulated with LMWH.[210] Warfarin should be initiated concurrently with LMWH, and LMWH should be continued until the INR

reaches the therapeutic range of 2 to 3. Warfarin should be continued for a duration specific to the individual patient's risk profile.[211]

Coronary Artery Bypass Surgery

Surgery after STEMI may carry substantial risk, particularly in unstable patients with Q-wave infarction and decreased LV function. Prior coronary artery bypass grafting, female gender, comorbidities, and advanced age are factors that compound this risk considerably.[212] Patients who have mechanical complications of myocardial infarction, such as ventricular septal rupture or papillary muscle rupture, or who have ongoing ischemia that has been unresponsive to other medical therapy and have vessels suitable for bypass, should undergo emergency surgery. Stable patients should have surgery delayed for 3 to 7 days to allow myocardial recovery to occur.

An internal mammary artery graft to a significantly stenosed left anterior descending artery should be used whenever possible owing to better long-term survival (see Chapter 8). Unstable patients undergoing CABG shortly after fibrinolytic therapy, primarily for continuing myocardial ischemia, have a higher operative mortality rate (13% to 17%) and increased use of blood products.[213] CABG should be considered when recurrent ischemia occurs in patients whose coronary artery anatomy is not suitable for PCI. Elective CABG improves survival relative to medical therapy in patients with MI who have (1) left main coronary artery stenosis; (2) left main equivalent disease (significant ≥70% stenosis of the proximal left anterior descending and proximal left circumflex artery); (3) three-vessel disease, particularly with decreased left ventricular function; (4) two-vessel disease with significant proximal left anterior descending stenosis, not amenable to PCI, and either ejection fraction <0.50% or demonstrable ischemia on noninvasive testing; and (5) one- or two-vessel disease, not amenable to PCI, without proximal left anterior descending stenosis but with a large area of viable myocardium at risk and high-risk criteria on noninvasive testing.[214] Aspirin should not be withheld before surgery, but if possible, clopidogrel should be withheld for 5 to 7 days.[40] Platelet aggregation returns to normal 4 hours after discontinuing eptifibatide or tirofiban. Platelet transfusions may need to be given to restore platelet function if surgery is performed within 24 hours of receiving abciximab because of its prolonged effect.

Risk Stratification

The purpose of risk stratification testing is to determine which patients are at increased risk for recurrent ischemic events, congestive heart failure, or sudden death. Major management decisions include whether to refer a patient for cardiac catheterization (Fig. 11–18) or for placement of an ICD (see Fig. 11–16).

Exercise Testing

Exercise testing may be performed to (1) predict the likelihood of a subsequent cardiac event; (2) establish exercise parameters for cardiac rehabilitation; (3) assess functional capacity and the patient's ability to perform tasks at home and at work; (4) evaluate recurrent chest pain; and (5) evaluate the efficacy of the patient's current medical regimen.[215]

Two different protocols have been used. Low-level exercise testing appears to be safe if patients have had no symptoms of angina or heart failure and have a stable baseline ECG 48 to 72 hours before the exercise test. The traditional submaximal exercise test is stopped when one of the following endpoints is reached: peak heart rate of 120 to 130 beats per minute or 70% of maximal predicted for age; peak work level of 5 METs; clinical endpoints of mild angina or dyspnea; ST-segment depression >2 mm; exertional hypotension; or three or more consecutive PVCs. The second protocol is performance of a symptom-limited exercise test in low-risk patients days to weeks after STEMI. Although this will result in a higher frequency of abnormal exercise tests, the prognostic value of ST-segment depression occurring at higher work levels in deconditioned patients is uncertain.

Baseline abnormalities that compromise ECG interpretation include >1 mm ST-segment depression on the resting tracing, LBBB, LV hypertrophy with strain, ventricular pre-excitation, and ventricular pacing. If exercise testing is performed in the presence of these abnormalities, echocardiography or myocardial perfusion imaging should be added. Exercise testing should not be performed within 2 to 3 days of STEMI in patients who have not undergone successful reperfusion. Exercise testing should not be performed to evaluate patients with STEMI who have unstable post-infarction angina, decompensated CHF, life-threatening cardiac arrhythmias, noncardiac conditions that severely limit their ability to exercise, or other absolute contraindications to exercise testing.

Echocardiography

Echocardiography should be used to assess both global and regional ventricular function in patients not undergoing contrast left ventriculography. It should also be used to evaluate suspected complications including RV infarction, acute mitral regurgitation, ventricular septal rupture, cardiogenic shock, infarct expansion, intracardiac thrombus, and pericardial effusion.[216,217]

The incremental value of exercise echocardiography over regular exercising testing after STEMI has not been established. However, echocardiography or perfusion imaging should be added to exercise testing whenever baseline abnormalities are expected to compromise electrocardiographic interpretation. Pharmacologic stress echocardiography using a graded protocol and beginning at low doses of dobutamine can be substituted for exercise in pre-discharge functional testing for ischemia in patients with limited exercise capacity and can help in assessing myocardial viability early after STEMI.

Myocardial Perfusion Imaging

When baseline abnormalities are expected to compromise electrocardiographic exercise test interpretation, myocardial perfusion imaging or echocardiography should be added. An advantage for nuclear scintigraphy is the quantitative measurement of LVEF. Data are also emerging to suggest that dipyridamole or adenosine stress perfusion nuclear scintigraphy is safe and can be used for early (48 to 72 hours) risk stratification.[218]

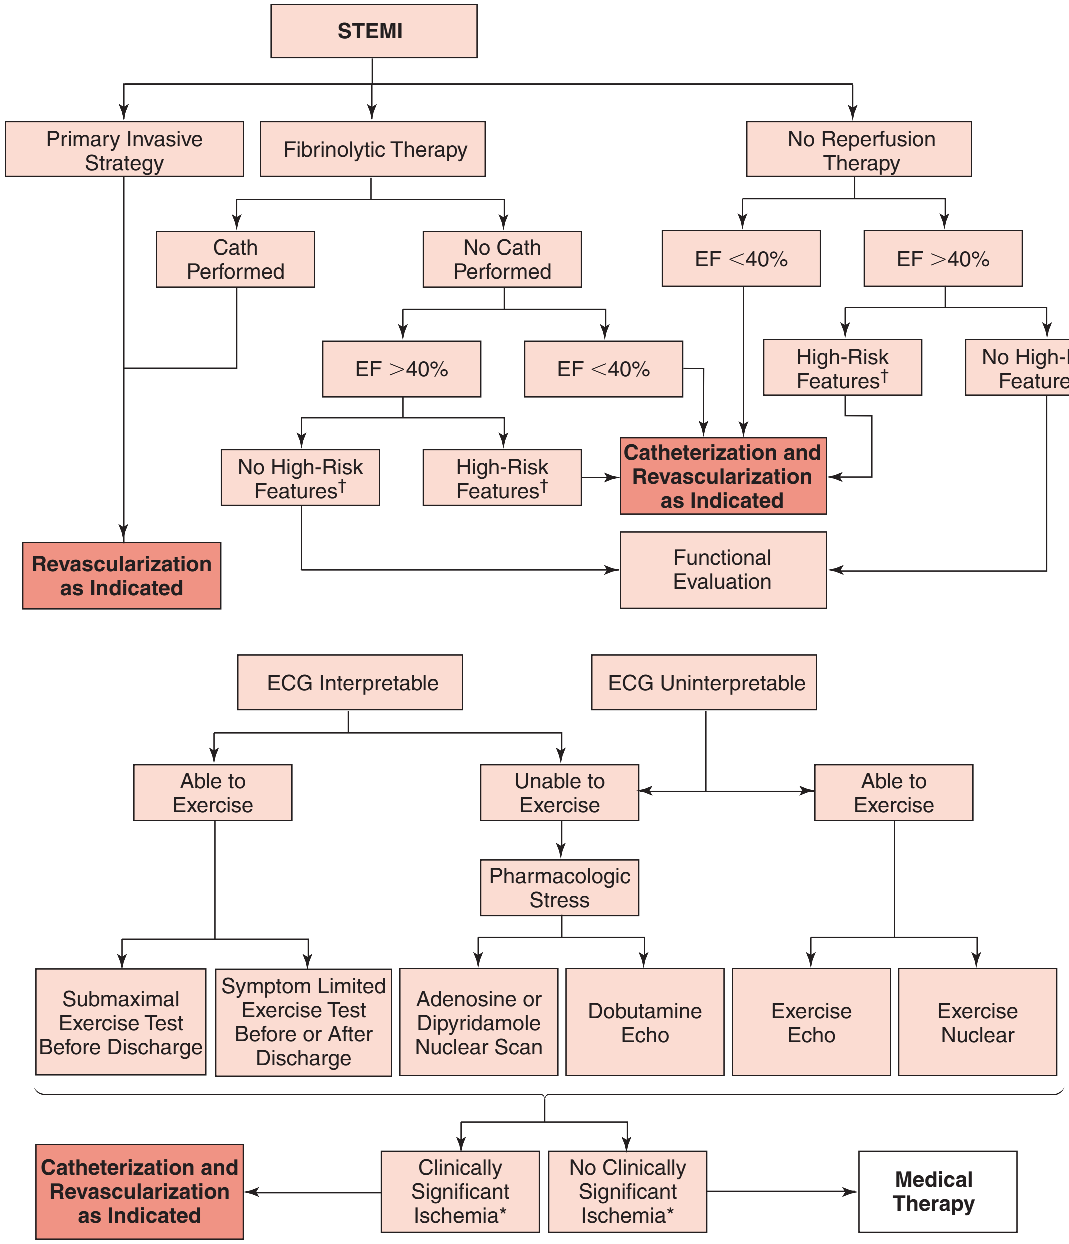

Figure 11–18 Evidence-based approach to need for catheterization (cath) and revascularization after ST-elevation myocardial infarction (STEMI). The algorithm shows treatment paths for patients who initially undergo a primary invasive strategy, receive fibrinolytic therapy, or do not undergo reperfusion therapy for STEMI. Patients who have not undergone a primary invasive strategy and have no high-risk features should undergo functional evaluation with one of the noninvasive tests shown. When clinically significant ischemia is detected, patients should undergo catheterization and revascularization as indicated; if no clinically significant ischemia is detected, medical therapy is prescribed after STEMI. *Please see Table 23 of the ACC/AHA 2002 Guideline Update for the Management of Patients with Chronic Stable Angina for further definition. (Adapted from Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee to revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction]. Circulation 2004;588-636, with permission.)

Left Ventricular Function

Assessment of LV function after STEMI has been shown to be one of the most accurate predictors of future cardiac events.[219] The assessment can include such basic factors as clinical estimates based on the patient's symptoms (exertional dyspnea, functional status) and physical findings (rales, murmurs, elevated jugular venous pressure, cardiomegaly, S3 gallop). Measurement of LVEF by contrast ventriculography, radionuclide ventriculography, and two-dimensional echocardiography has important prognostic value. Because of the dynamic nature of LV function recovery after STEMI, the

timing of the imaging study needs to be considered. An LVEF <0.40 is an indication for ACE inhibitor therapy and a reduced EF is useful for identifying candidates for an ICD (see Fig. 11–16). Post-infarction LV dilation, demonstrated by increased end-systolic volume >130 mL, may be a better predictor of mortality after MI than an LVEF <0.40 or increased end-diastolic volume.[220]

Myocardial Viability

In some patients, viable but dysfunctional myocardium contributes to LV dysfunction and may be significantly reversible with revascularization. Processes of myocardial hibernation (chronic low flow states associated with depressed myocardial function)[221] and stunning (depression of ventricular function after acute ischemia despite adequate restoration of blood flow)[222] contribute to the potential reversibility of ventricular function. Radionuclide imaging and dobutamine echocardiography can identify patients most likely to benefit from revascularization.[223] Positron emission tomography[224] and contrast-enhanced magnetic resonance imaging[225] are promising experimental techniques. However, more conclusive diagnostic efficacy studies are needed to demonstrate patient benefit from viability testing before it becomes standard testing.

Invasive Evaluation

All survivors of STEMI who are candidates for revascularization therapy with spontaneous ischemia, intermediate- or high-risk findings on noninvasive testing, hemodynamic or electrical instability, mechanical defects, earlier revascularization, or high-risk clinical features should be considered for coronary arteriography. PCI or CABG may be considered in these patients if they are found to have significant obstructive coronary artery disease. Previous randomized trials testing a strategy of routine catheterization after fibrinolytic therapy suggested that such an approach was deleterious.[226-230] However, those trials were conducted in an era when aspirin was inconsistently administered, high doses of UFH without ACT monitoring were used, and the interventional catheters, radiographic imaging equipment, and supportive antiplatelet agents were suboptimal. Subsequent data suggest that the early invasive strategy is associated with a lower risk of recurrent MI and death (see Fig. 11–7B).[197]

Assessment of Electrical Substrate

A number of noninvasive strategies have been used to identify patients at high risk for arrhythmic events. Signal-averaged electrocardiography identifies delayed, fragmented conduction in the infarct zone in the form of late potentials at the terminus of the QRS complex and represents an anatomic substrate that predisposes the patient to reentrant VT.[231] Heart rate variability, an analysis of the beat-to-beat variation in cycle length, largely reflects the sympathovagal interaction regulating heart rate. Low heart rate variability, indicative of decreased vagal tone, is a predictor of increased mortality, including sudden death, in patients after MI.[232] Baroreceptor sensitivity also quantifies the influence of parasympathetic tone on the heart. It is measured as the slope of a regression line that relates beat-to-beat heart rate change in response to a change in blood pressure, often accomplished by giving a small bolus of phenylephrine.[233] Abnormalities in ventricular repolarization are detectable by microvolt alterations of T wave amplitude, or T wave alternans, and have been shown to be associated with inducible ventricular arrhythmias during programmed ventricular stimulation and spontaneous arrhythmic events.[234] The clinical importance of these tests has yet to be determined.

LONG-TERM MANAGEMENT

Risk Factor Control

Secondary prevention therapies are an essential part of the management of all patients with STEMI. (Table 11–9) Because atherosclerotic vascular disease is frequently found in multiple vascular beds, the physician should also search for symptoms or signs of peripheral vascular disease or cerebrovascular disease in patients with STEMI. Approximately 70% of CHD deaths and 50% of MIs occur in patients who have previously established coronary artery disease.[2] It is estimated that the likelihood of fatal and nonfatal MI is four to six times higher in patients with apparent coronary disease. Within 6 years after a recognized heart attack, 18% of men and 35% of women will have another heart attack[2]; most episodes of cardiac arrest occur within 18 months after hospital discharge for STEMI.[235] Therefore, the institution of secondary prevention therapies and risk reduction strategies in patients recovering from STEMI represent major opportunities to reduce the toll of cardiovascular disease.

Weight Management

Obesity is a recognized major risk factor for cardiovascular disease and an important component of the metabolic syndrome. The diagnosis of metabolic syndrome includes three of the following: waist circumference >40 inches in men and >35 inches in women; TG ≥250/dL; HDL <40 mg/dL in men or <50 mg/dL in women; blood pressure >130/85 mm Hg; and fasting blood glucose ≥110 mg/dL. The primary treatment strategies are calorie control and physical activity. A desirable BMI range is 18.5 to 24.9 kg/m^2. Weight loss should be part of the cardiac rehabilitation program after STEMI with a goal of losing 10% of body weight over 6 months at a rate of 1 to 2 pounds each week.

Smoking Cessation

Smoking increases coronary vasomotor tone, reduces the anti-ischemic effects of β-adrenoceptor blockers, and doubles mortality after STEMI.[236] Smoking cessation reduces rates of reinfarction and death within a year of quitting, but one third to one half of patients relapse within 6 to 12 months.[237] Family members who live in the same household should also be encouraged to quit smoking to help reinforce the patient's effort and to decrease the risk of second-hand smoke. The most effective pharmacologic adjuncts for treating nicotine dependence are nicotine replacement therapy (gums and patches) and bupropion, combined with behavioral counseling.[238]

Table 11–9 Secondary Prevention for Patients with STEMI

Goals	Intervention Recommendations
Smoking *Goal:* Complete cessation	Assess tobacco use. Strongly encourage patient and family to stop smoking and to avoid second-hand smoke. Provide counseling, pharmacologic therapy (including nicotine replacement and bupropion) and formal smoking cessation programs as appropriate.
Blood pressure control: *Goal:* <140/90 mm Hg or <130/80 mm Hg if chronic kidney disease or diabetes	If blood pressure is 120/80 mm Hg or greater: • Initiate lifestyle modification (weight control, physical activity, alcohol moderation, moderate sodium restriction, and emphasis on fruits, vegetables, and low-fat dairy products) in all patients. If blood pressure is 140/90 mm Hg or greater or 130/80 mm Hg or greater for individuals with chronic kidney disease or diabetes • Add blood pressure-reducing medications, emphasizing the use of β-blockers and inhibitors of the renin-angiotensin-aldosterone system.
Lipid management: (TG < 200 mg/dL) *Primary goal:* LDL-C substantially <100 mg/dL and preferably ≤70 mg/dL	Start dietary therapy in all patients (<7% of total calories as saturated fat and <200 mg/day cholesterol). Promote physical activity and weight management. Encourage increased consumption of omega-3 fatty acids. Assess fasting lipid profile in all patients, preferably within 24 hours of STEMI. Add drug therapy according to the following guide: LDL-C <100 mg/dL (baseline or on-treatment): • Statins should be used to lower LDL-C LDL-C ≥100 mg/dL (baseline or on-treatment): • Intensify LDL-C-lowering therapy with drug treatment, giving preference to statins.
Lipid management: (TG 200 mg/dL or greater) *Primary goal:* Non-HDL-C* <130 mg/dL	If TGs are ≥150 mg/dL or HDL-C is <40 mg/dL: • Emphasize weight management and physical activity. Advise smoking cessation. If TG is 200–499 mg/dL: • After LDL-lowering therapy,† consider adding fibrate or niacin‡ If TG is ≥ 500 mg/dL: • Consider fibrate or niacin‡ before LDL-C-lowering therapy† • Consider omega-3 fatty acids as adjunct for high TG
Physical activity: *Minimum goal:* 30 minutes 3 to 4 days per week Optimal daily	Assess risk, preferably with exercise test, to guide prescription. Encourage minimum of 30 to 60 minutes of activity, preferably daily, or at least 3 or 4 times weekly (walking, jogging, cycling, or other aerobic activity) supplemented by an increase in daily lifestyle activities (walking breaks at work, gardening, household work). Cardiac rehabilitation programs are recommended for patients with STEMI, particularly those with multiple modifiable risk factors and/or those moderate- to high-risk patients in whom supervised exercise training is warranted.
Weight management: *Goal:* BMI 18.5-24.9 kg/m^2 Waist circumference: Women: <35 inches Men: <40 inches	Calculate BMI and measure waist circumference as part of evaluation. Monitor response of BMI and waist circumference to therapy. Start weight management and physical activity as appropriate. Desirable BMI range is 18.5–24.9 kg/m^2. If waist circumference is ≥35 inches in women or ≥40 inches in men, initiate lifestyle changes and treatment strategies for metabolic syndrome.
Diabetes management: *Goal:* $HbA1_c$<7%	Appropriate hypoglycemic therapy to achieve near-normal fasting plasma glucose, as indicated by HbA1c. Treatment of other risk factors (physical activity, weight management, blood pressure, and cholesterol management).
Antiplatelet Agents/Anticoagulants	Start and continue indefinitely aspirin 75 to 162 mg/day if not contraindicated. Start clopidogrel 75 mg/day. Manage warfarin to INR 2.5 to 3.5 in post-STEMI patients when clinically indicated or for those not able to take aspirin or clopidogrel.

Lipid Management

Dietary therapy that is low in saturated fat and cholesterol (<7% of total calories as saturated fat and <200 mg/day cholesterol) should be started after recovery from STEMI. Patients should increase consumption of omega-3 fatty acids, fruits, vegetables, soluble (viscous) fiber, and whole grains. The Heart Protection Study[239] and the PROVE-IT-TIMI 22 trial,[240] among others,[241] suggest that the goal for statin therapy in these patients should be to lower the LDL cho-

Table 11–9 Secondary Prevention for Patients with STEMI—cont'd

Goals	Intervention Recommendations
Renin-Angiotensin-Aldosterone System Blockers:	ACE inhibitors in all patients indefinitely; start early in stable high-risk patients (anterior MI, previous MI, Killip ≥II [S3 gallop, rales, radiographic CHF], LVEF <0.40). Angiotensin-receptor blockers in patients who are intolerant of ACE inhibitors and with either clinical or radiologic signs of CHF or LVEF <0.40. Aldosterone blockade in patients without significant renal dysfunction§ or hyperkalemia‖ who are already receiving therapeutic doses of an ACE inhibitor, have an ≤0.40, and have either diabetes or heart failure.
β-Blockers:	Start in all patients. Continue indefinitely. Observe usual contraindications.

*Non-HDL-C, total cholesterol minus HDL-C.
†Treat to a goal of non-HDL-C substantially <130 mg/dL
‡Dietary-supplement niacin must not be used as a substitute for prescription niacin, and over-the-counter niacin should be used only if approved and monitored by a physician.
§Creatinine should be ≤2.5 mg/dL in men or ≤2.0 mg/dL in women.
‖Potassium should be <5.0 mEq/L.
ACE, angiotensin-converting enzyme; BMI, body mass index; CHF, congestive heart failure; HDL-C, high-density lipoprotein cholesterol; INR, international normalized ratio; LDL-C, low-density lipoprotein cholesterol; LVEF, left ventricular ejection fraction; STEMI, ST-elevation myocardial infarction; TG, triglycerides.
Modified from Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction). Circulation 2004;110:588-636.

lesterol to 70 mg/dL. Approximately 25% of patients who have recovered from STEMI demonstrate desirable total cholesterol values but a low HDL level. Low HDL is an independent risk factor for the development for CAD.[242] Patients with non-HDL cholesterol levels <130 mg/dL who have HDL levels <40 mg/dL should receive special emphasis on nonpharmacologic therapy (i.e., exercise, weight loss) to increase HDL. Those who do not respond may be started on fibrates or niacin. It is reasonable to add either niacin or fibrates to the diet regardless of LDL and HDL levels when triglyceride levels are >500 mg/dL. In this setting, non-HDL cholesterol (goal <130 mg/dL) should be the cholesterol target, rather than LDL. Diet and drug treatment are also effective in the elderly.[243] Patients started on lipid-lowering therapy before hospital discharge are three times more likely to be taking medication at 6 months than those who start therapy after discharge.[244]

Blood Pressure Control

Lifestyle modifications for patients with blood pressure >120/80 mm Hg include weight reduction if overweight or obese; consumption of a diet rich in fruits and vegetables and low in total fat and saturated fat; and reduction of sodium to no more than 2.4 g/day. A diet rich in potassium and calcium is also recommended for those with normal renal function. After STEMI, patients should be treated with β-blockers, ACE inhibitors (or ARBs if ACE inhibitors are not tolerated), and, if necessary, aldosterone antagonists to a target BP of <140/90 mm Hg. Patients with chronic kidney disease or diabetes should be treated to a target <130/80 mm Hg.[245] Most patients will require two or more drugs to reach goal, and when the BP is >20/10 mm Hg above goal, two drugs should usually be used from the outset. Thiazides or long-acting calcium channel blockers may be used if other agents are not tolerated or are not sufficient to reach BP goal. Short-acting calcium antagonists should not be used.

Diabetes Management

Tight glucose control (HbA1c <7.0%) in diabetics during and after STEMI has been shown to lower acute and 1-year mortality rates.[246] Thiazolidinediones are frequently used as monotherapy or in combination with other oral hypoglycemic agents, insulin, and diet for control of diabetes. Thiazolidinediones may also be associated with fluid retention and an increase in left ventricular preload[247] that is resistant to diuretics, so they should not be used in patients recovering from STEMI who have NYHA class III or IV heart failure.[248] Patients with heart failure and/or significant renal insufficiency should not be placed on metformin.

Medications

Antiplatelet Agents

The Antiplatelet Trialists' Collaboration reported a 25% reduction in the risk of recurrent infarction, stroke, or vascular death in patients who received prolonged antiplatelet therapy (36 fewer events for every 1000 patients treated).[36] No antiplatelet therapy has proved superior to aspirin, and daily doses of aspirin between 75 and 160 mg should be continued indefinitely. The salutary effect of aspirin may be diminished by the concomitant use of ibuprofen and other NSAIDs[249,250] and this combination should be discouraged. Clopidogrel is the best alternative to aspirin in patients who have a true aspirin allergy.[251] Dual antiplatelet therapy with aspirin and clopidogrel should be continued for several weeks in patients who are not treated with PCI and for several months in patients who receive PCI.[38,39]

β-Blockers

The benefits of β-blocker therapy in patients without contraindications are well established with or without reperfusion therapy and in all age groups. The greatest mortality benefit is seen in patients with impaired left ventricular function, ventricular arrhythmias, and occluded infarct arteries. The benefit is less in low-risk patients, but β-blockers may still minimize the likelihood of recurrent ischemic symptoms and control heart rate and blood pressure during exertion. In patients with moderate or severe LV failure, β-blocker therapy should be administered using a gradual titration scheme.[252] Even when relative contraindications exist (mild asthma not currently active, insulin-dependent diabetes, chronic obstructive pulmonary disease, peripheral vascular disease, PR interval >0.24 seconds, moderate LV failure), the benefit in reducing mortality and reinfarction with β-blocker therapy may outweigh the risks. Data from large trials suggest that therapy should be continued for at least 2 to 3 years and probably should be continued indefinitely.

Statins

Statin therapy reduces the risk of myocardial infarction, stroke, and death in all subgroups.[240,253-255] Benefit has been shown at all levels of LDL, although the greatest benefit was seen with LDL >125 mg/dL. A strong argument can be made for starting all patients on statin therapy, regardless of their LDL level. The treatment goal should be a LDL level substantially <100 mg/dL and probably closer to 70 mg/dL.[240]

Inhibition of the Renin-Angiotensin-Aldosterone System

ACE inhibitors inhibit ventricular remodeling and dilatation after STEMI and should be prescribed at discharge for all patients without contraindications to decrease the risk of MI, CHF, and death.[256-259] Although the largest benefit appears to be in those with ejection fractions below 40% and with anterior MI, other trials have shown benefit in patients without known left ventricular dysfunction or CHF.[260,261]

Angiotensin receptor blockers should be prescribed for those STEMI patients who are intolerant of ACE inhibitors and have either clinical or radiologic signs of heart failure and a LVEF >40%. Valsartan[262] may be initiated at 20 mg/day and titrated to a maximum of 160 mg twice a day. Candesartan[263] can be initiated at 4 to 8 mg daily and titrated to 32 mg daily.

An aldosterone inhibitor (spironolactone—target dose 50 mg or eplerenone—target dose 50 mg) should be added to an ACE inhibitor or ARB in patients with LVEF <40% and CHF or diabetes, provided the serum creatinine is <2.5 mg/dL in men, or 2.0 mg/dL in women, and the serum potassium is <5.0 mEq/L.[124,125]

Warfarin

The indications for long-term anticoagulation after STEMI are controversial and evolving. Markers of thrombin generation remain elevated after STEMI and recurrent ischemic events occur even in the presence of aspirin and clopidogrel. In the APRICOT study,[264] the use of medium intensity warfarin (INR 2 to 3) plus aspirin resulted in less infarct artery reocclusion after fibrinolytic therapy and a significant reduction in the combined endpoints of death, MI, and revascularization versus aspirin alone. The WARIS II trial[265] compared high-intensity warfarin (INR 2.8 to 4.2) alone, medium-intensity warfarin (INR 2 to 2.5) plus aspirin 81 mg, and aspirin 160 mg alone. There was a significant reduction in nonfatal MI and nonfatal thromboembolic stroke with warfarin, but bleeding was more common and a significant number of patients discontinued therapy. Patients >75 years of age have not been adequately studied.

When the physician thinks that there is a significant risk for reinfarction or thromboembolic events and a low risk for bleeding in patients <75 years of age, it is reasonable to prescribe warfarin alone (INR 2.5 to 3.5) or warfarin (INR 2 to 3) in combination with aspirin 81 to 162 mg to those who can have their level of anticoagulation monitored reliably (Fig. 11–19). Warfarin may be used in aspirin-allergic patients who have indications for anticoagulation. Warfarin should be used in STEMI patients with persistent or paroxysmal AF. It should be prescribed for LV thrombus noted on an imaging study for at least 3 months and may be useful when extensive regional wall motion abnormalities are present. When the combination of warfarin, aspirin, and clopidogrel is required, clopidogrel should be stopped as soon as possible.[266,267]

Hormone Replacement Therapy

Postmenopausal women should not receive combination estrogen and progestin therapy for secondary prevention.[268,269] It is recommended to discontinue use of hormone therapy for women who have STEMI.[270] Women who are beyond 1 to 2 years post-initiation of hormone therapy and wish to continue it should weigh the risks and benefits, recognizing a greater risk of cardiovascular events. Hormone therapy should not be continued while patients are at bed rest in the hospital because of the increased risk for venous thromboembolic events.

Antioxidants

Vitamin E supplementation does not reduce cardiac events after STEMI,[271] nor are there data supporting vitamin C supplementation. Beta carotene has no beneficial effect and may increase the risk of lung cancer.[272] The use of either lipid- or water-soluble antioxidant supplementation should be discouraged.

Functional Status

Physical Activity

Walking can be encouraged immediately after discharge. In stable uncomplicated patients, sexual activity with the usual partner can be resumed within 1 week to 10 days. Driving can begin a week after discharge if the patient is judged to be in compliance with individual state laws. Air travel within the first 2 weeks of STEMI should be undertaken only in the absence of angina or dyspnea at rest. Based on assessment of risk, ideally with an exercise test to guide the prescription, all patients recovering from STEMI should be encouraged to exercise for a minimum of 30 minutes, preferably daily, but at

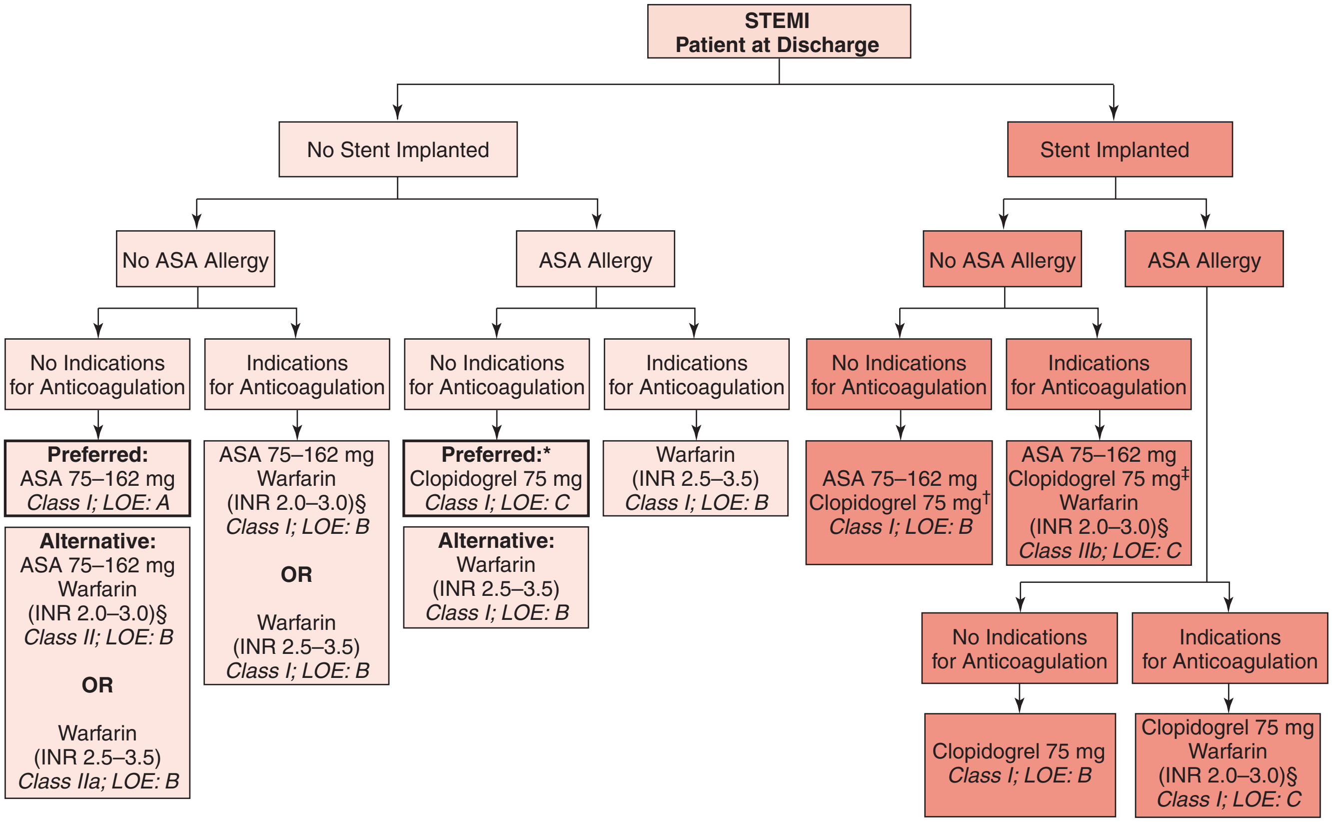

Figure 11–19 Long-term antithrombotic therapy at hospital discharge after ST-elevation myocardial infarction (STEMI). *Clopidogrel is preferred over warfarin because of increased risk of bleeding and low patient compliance in warfarin trials. †For 12 months. ‡Discontinue clopidogrel 1 month after implantation of a bare-metal stent or several months after implantation of a drug-eluting stent (3 months after sirolimus and 6 months after paclitaxel) because of the potential increased risk of bleeding with warfarin and two antiplatelet agents. Continue aspirin and warfarin long term if warfarin is indicated for other associated reasons such as atrial fibrillation, LV thrombus, cerebral emboli, or extensive regional wall-motion abnormality. §An INR of 2.0 to 3.0 is acceptable with tight control, but the lower end of this range is preferable. The combination of antiplatelet therapy and warfarin may be considered in patients <75 years of age with low bleeding risk who can be monitored reliably. ASA, aspirin; INR, international normalized ratio; LOE , level of evidence. (Adapted from Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee to revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction]. Circulation 2004;110:588-636, with permission.)

least 3 or 4 times per week (walking, jogging, cycling, or other aerobic activity). The 30 minutes can be spread out over two or three segments during the day. This should be supplemented by an increase in daily lifestyle activities (such as walking breaks at work, gardening, household work). Patients also require specific instruction on strenuous activities (such as heavy lifting, climbing stairs, yard work, household activities) that are permissible and those they should avoid. In addition to aerobic training, mild-to-moderate resistance training is also recommended. This can be started 2 to 4 weeks after aerobic training has begun.[273]

Cardiac Rehabilitation

Comprehensive cardiac rehabilitation services include long-term programs that involve medical evaluation, prescribed exercise, cardiac risk factor modification, education, and counseling.[274] These programs are designed to limit the physiologic and psychological effects of cardiac illness, reduce the risk for sudden death or reinfarction, control cardiac symptoms, stabilize or reverse the atherosclerotic process, and enhance the psychosocial and vocational status of select patients. Enrollment in a cardiac rehabilitation program after discharge may enhance patient education and compliance with the medical regimen as well as assist with the implementation of a regular exercise program. A cardiac rehabilitation program is recommended for all patients, particularly for those with multiple modifiable risk factors and/or for those moderate- to high-risk patients in whom supervised exercise training is warranted.

Psychosocial Impact

Major depression may occur in 15% to 20% of patients and minor depression in as many as 50%.[275] These patients are more likely to be rehospitalized within 1 year and have a decreased long-term survival. They are also less likely to complete cardiac rehabilitation, comply with lifestyle changes and

medication prescriptions, return to work, or resume a normal quality of life. Therefore, the psychosocial status of the patient should be evaluated, including inquiries regarding symptoms of depression, anxiety, or sleep disorders, and the social support environment. Treatment of depression with combined cognitive-behavioral therapy and selective serotonin reuptake inhibitors improves outcome in terms of depressive symptoms and social function.[276]

Follow-Up Visit

A caring and supportive doctor–patient relationship is vital to the well-being of the survivors and their families. It is common practice to see these patients 3 to 6 weeks after hospital discharge to assess their progress. The following issues should be addressed: (1) the presence or absence of cardiovascular symptoms and the functional state of the patient should be delineated; (2) the list of current medications should be verified and reevaluated—doses of β-blockers, ACE inhibitors, and statins should be titrated when appropriate; (3) the risk assessment work-up should be completed and reviewed—this should include a check of LV function and possibly Holter monitoring for those patients whose early post-STEMI ejection fraction was 30% to 40% or lower, in consideration of possible ICD use; (4) the physician should review the principles of secondary prevention with the patient and the family; (5) the psychosocial status of the patient should be evaluated including inquiries regarding symptoms of depression, anxiety, sleep disorders, and the social support environment—appropriate therapy with cognitive-behavioral therapy and antidepressants should be initiated if indicated; (6) discussion of the resumption of physical activity, return to work, resumption of sexual activity, and travel should occur; (7) patients and their families should be asked if they are interested in CPR and AED training; (8) the physician should review with the patient the risk of reinfarction, symptoms of angina and STEMI, and the advisability of calling 911 if symptoms are unimproved or worsening 5 minutes after a sublingual nitroglycerin tablet; and (9) cardiac rehabilitation programs, where available and appropriate, should be recommended.

Return to Work and Disability

Return to work rates and disability rates are influenced by multiple factors. Besides the cardiac functional status of the patient, factors such as age, depressive symptoms, job security, job satisfaction, financial stability, and company policies all influence the ability and decision to return to work.

Chronic Stable Angina

David E. Newby and Keith A. A. Fox

CHAPTER CONTENTS

Stable or predictable angina on effort occurs not only in the setting of a fixed atherosclerotic stenosis but also in other conditions such as aortic stenosis, mitral valve prolapse, and hypertrophic cardiomyopathy. In this chapter, we discuss chronic stable angina principally in relation to obstructive coronary atheroma. It should, however, be recognized that other forms of angina exist (Table 12–1) and that vasospasm associated with nonobstructive atheromatous plaques can occur.

EPIDEMIOLOGY

Coronary atherosclerosis is associated with many risk factors, such as cigarette smoking, hyperlipidemia, family history, hypertension, and diabetes mellitus (see Chapter 9).[1] The prevalence and extent of coronary atheroma and angina pectoris increase with age and have a male preponderance.[2] Distribution among ethnic groups is unequal, with higher rates in Indo-Asians and lower rates in East Asians and Afro-Caribbeans compared with whites.[3]

The epidemiology of coronary artery disease and angina pectoris is changing. In some regions of the world, such as North America, Western Europe, Japan, and Australia, the incidence, mortality rates, and in-hospital case fatalities are declining,[4] although the overall prevalence of coronary artery disease is still rising—in keeping with an aging population. However, Eastern Europe, in particular, is experiencing escalating rates of coronary artery disease and associated mortality rates.

NATURAL HISTORY

Angina pectoris results in substantial morbidity. In two thirds of patients, angina has significant effects on the ability to work and to undertake recreational, sexual, and other daily activities. On average, a patient with angina pectoris will consult a primary health care professional two or three times each year. The complications of angina pectoris in part relate to the extent and severity of coronary artery disease and include MI, congestive heart failure, dysrhythmias, and sudden cardiac death. In general, patients with stable angina pectoris have a 2.5% to 5% risk of death or nonfatal myocardial infarction (MI) each year.[5,6]

The likelihood of sustaining an acute MI increases with the severity and extent of atheromatous involvement of the coronary arteries (Fig. 12–1). In addition, left ventricular function and the frequency and severity of angina (Figs. 12–2 and 12–3), as well as demographics such as age and gender, all influence the risk of MI.[7,8]

ASSESSMENT AND INVESTIGATION

Clinical Assessment

In patients with chronic stable angina, episodes of angina are usually initiated at consistent levels of physical stress and promptly disappear with cessation of activity (Table 12–2). Worsening angina provoked by progressively less exertion, over a short period of time, often culminating in pain at rest, is indicative of unstable angina (see Chapter 10).

The likelihood of coronary artery disease as the etiologic factor in the presence of chest pain is increased by the presence of established risk factors. Beyond stigmata of hyperlipidemia (rare) or signs of peripheral atheromatous vascular disease, there usually are no physical signs of angina. However, patients should be examined for signs of other possible causes of anginal chest pain, such as aortic stenosis and hypertrophic obstructive cardiomyopathy.

Risk Stratification

Clinical Indicators

There are a number of clinical indicators that identify patients who are at a relatively high risk for clinical events (Table 12–3 and Fig. 12–4). The threshold for the consideration of coronary angiography should, therefore, be lower in high-risk patients than in those being considered purely on the basis of their symptoms. The list of high-risk indicators in Table 12–3 is not comprehensive but incorporates the principal factors that determine risk.

Noninvasive Evaluation

Resting Electrocardiogram

A resting electrocardiogram (ECG) should always be recorded as part of the diagnostic evaluation of patients with chronic stable angina. (The resting ECG may also be useful for

Table 12–1 Causes of Anginal Chest Pain Not Attributable to a Fixed Atheromatous Stenosis of the Coronary Artery

Vascular Disorders	Cardiac Disorders
Variant angina Atheroma-associated vasospasm Microvascular angina, or syndrome X	Hypertrophic cardiomyopathy Aortic stenosis Hypertensive heart disease and left ventricular hypertrophy Mitral valve prolapse Severe pulmonary hypertension and right ventricular hypertrophy

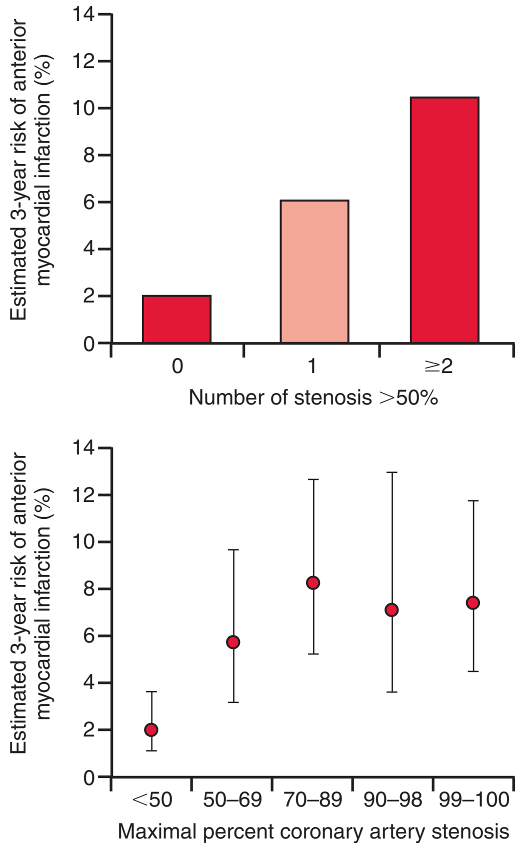

Figure 12–1 Three-year risk of anterior myocardial infarction according to the number *(top)* and severity (*bottom;* mean ± 95% confidence interval) of coronary artery stenoses in the left anterior descending coronary artery. (Data from Ellis S, Alderman E, Cain K, et al: Prediction of risk of anterior myocardial infarction by lesion severity and measurement method of stenoses in the left anterior descending coronary distribution: A CASS Registry study. J Am Coll Cardiol 1988;11:908.)

adjusting medical therapy, e.g., titration of dose of β-blocker). Although the sensitivity of the ECG is low for the diagnosis of ischemic heart disease—normal in almost one half of patients presenting with ischemic heart disease[9]—it does provide prognostic information. Resting ST-segment depression predicts an increased likelihood of subsequent MI and death.[10] Patients with evidence of previous MI or ST-T wave abnormalities without transmural Q-wave MI have a reduced survival rate.[11,12]

Table 12–2 Canadian Cardiovascular Society Functional Classification of Stable Angina Pectoris

Class 1	Ordinary physical activity, such as walking and climbing stairs, does not cause angina. Angina with strenuous or rapid or prolonged exertion at work or recreation.
Class 2	Slight limitation of ordinary activity. Walking or climbing stairs rapidly, walking uphill, walking or stair climbing after meals, in cold, in wind, or when under emotional stress, or only during the few hours after awakening. Walking more than two blocks on the level and climbing more than one flight of ordinary stairs at a normal pace and in normal conditions.
Class 3	Marked limitation of ordinary physical activity. Walking one to two blocks on the level and climbing more than one flight in normal conditions.
Class 4	Inability to carry on any physical activity without discomfort (anginal syndrome may be present at rest).

From Cox J, Naylor CD: The Canadian Cardiovascular Society grading scale for angina pectoris: Is it time for refinements? Ann Intern Med 1992;117:677.

Table 12–3 Clinical Indicators of Adverse Prognosis in Patients with Chronic Stable Angina

- Previous myocardial infarction
- Recent episode of unstable angina or new-onset stable angina
- Coexisting heart failure or evidence of left ventricular dysfunction
- Coexisting risk factors for coronary artery disease, such as hypertension and diabetes mellitus
- Age—the likelihood of death or nonfatal ischemic event increases with age
- Family history—independent predictor of death
- Pattern of anginal symptoms—quiescent angina is associated with a reduced risk of death and cardiac ischemic events

Exercise Electrocardiogram

Exercise testing is usually performed for two principal reasons: the diagnosis of ischemic heart disease and an assessment of the prognosis. It is an inappropriate screening test for ischemic heart disease when used in isolation. In a population

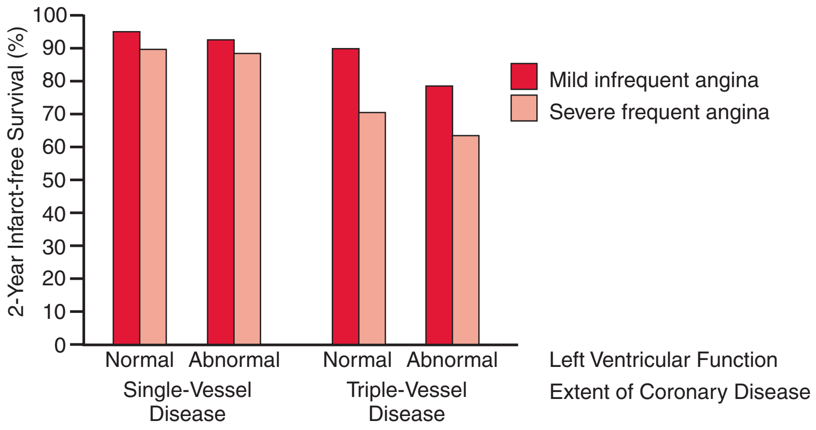

Figure 12–2 Two-year infarction-free survival rate of patients with angina pectoris according to angina frequency, extent of coronary artery disease, and left ventricular function (ejection fraction: normal, ≥50%; abnormal, <50%). (Data from Califf RM, Mark DB, Harrell FE, et al: Importance of clinical measures of ischemia in the prognosis of patients with documented coronary artery disease. J Am Coll Cardiol 1988;11:20.)

with a low prevalence of ischemic heart disease, the false-positive rate is high, particularly in the absence of symptoms (Fig. 12–5). The false-positive rate is also higher in younger individuals and in women.

The clinical context, associated symptoms, and overall cardiovascular response to exercise can be as important as the electrocardiographic response to exercise itself (Table 12–4). When used appropriately, exercise testing is a reliable, easily performed, and robust method of risk stratification in patients with stable angina.[7,13-15] It is a particularly useful method of identifying those individuals at highest risk and those who would benefit from further and potentially more invasive investigation and intervention (Fig. 12–6; see Fig. 12–4).

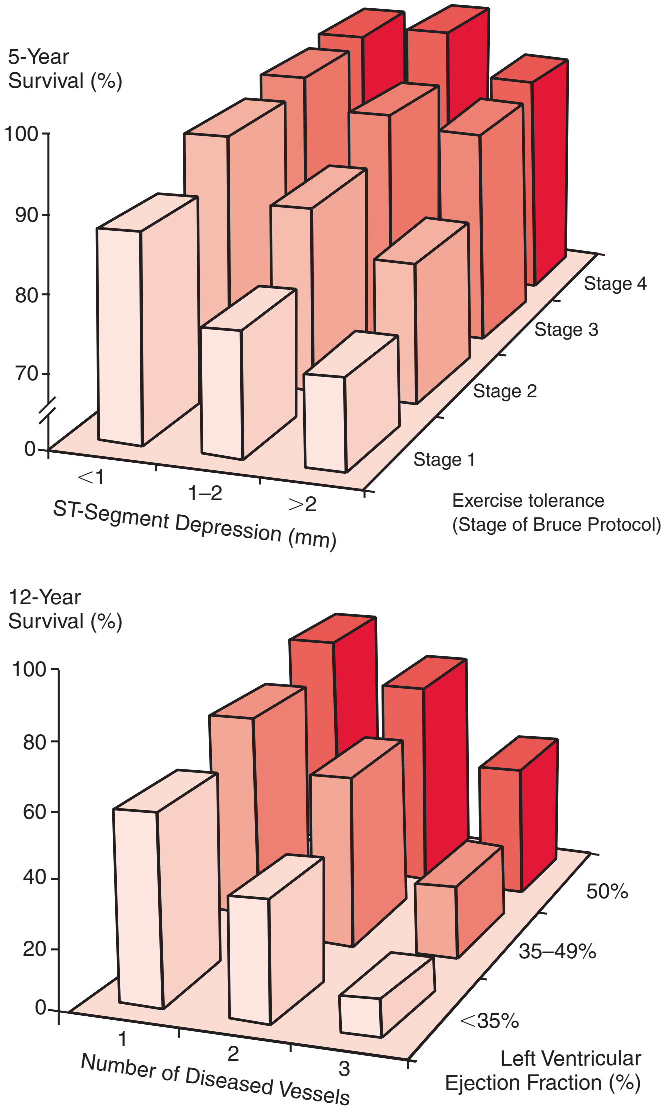

Figure 12–3 Five- and 12-year survival rates of medically treated patients according to exercise tolerance, exercise-induced ST-segment depression, number of diseased vessels, and left ventricular function. (Data from Emond M, Mock MB, David KB, et al: Long-term survival of medically treated patients in the Coronary Artery Surgery Study (CASS) Registry. Circulation 1994;90:2645; and Weiner DA, Ryan TJ, McCabe CH, et al: Prognostic importance of a clinical profile and exercise test in medically treated patients with coronary artery disease. J Am Coll Cardiol 1984;3:772.)

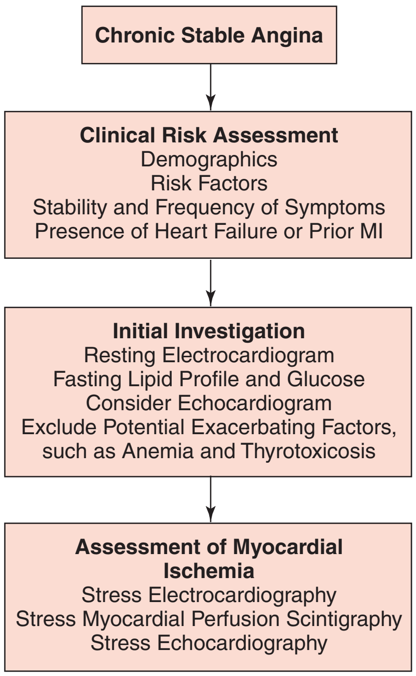

Figure 12–4 Schema for the initial assessment and investigation of patients with chronic stable angina. *Note:* When assessing the patient for provocable ischemia, clinicians should select one of the methods shown but not perform all three.

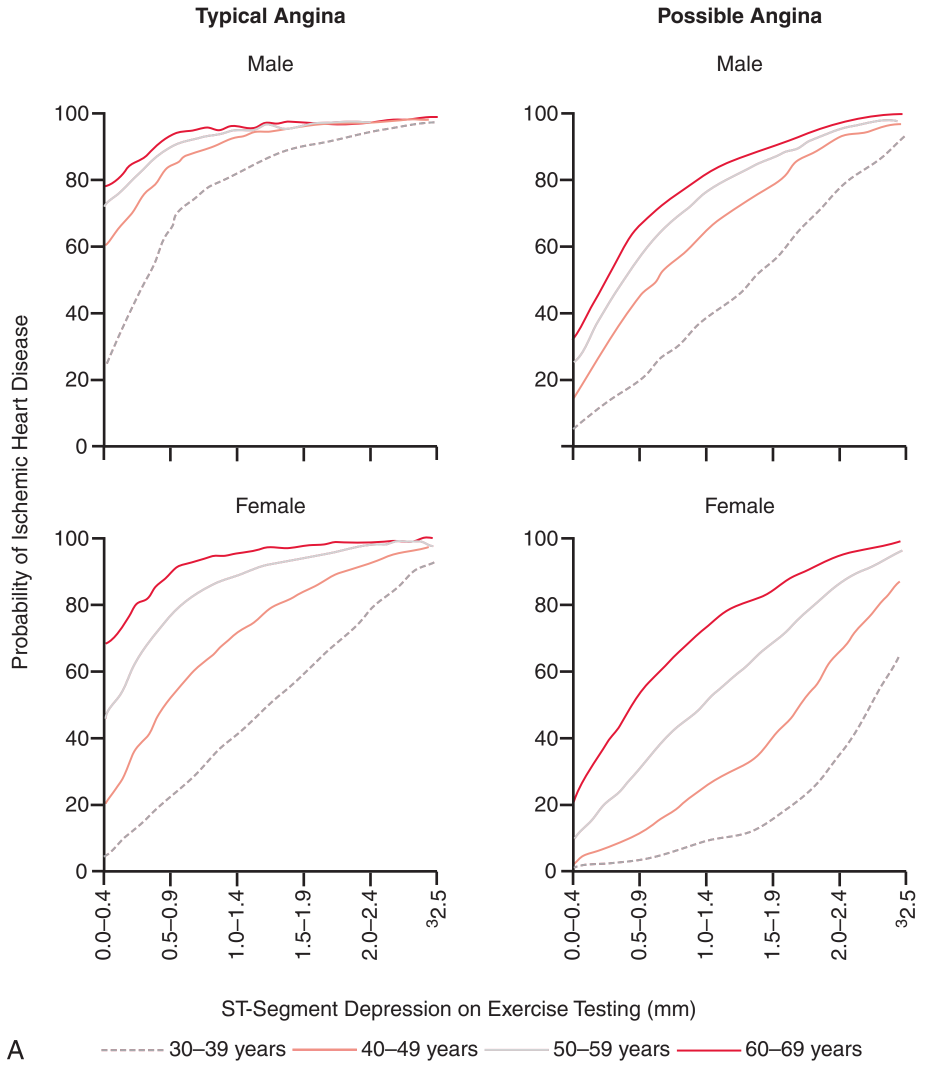

Figure 12–5 Probability of ischemic heart disease according to age, sex, clinical history, and exercise electrocardiographic ST-segment depression. Panel **A** depicts the probability of ischemic heart disease in patients presenting with either typical or possible angina (stratified by gender and age). Panel **B** is arranged similarly but for patients who present with atypical angina or who are asymptomatic. (Data from European Society of Cardiology Working Group on Exercise Physiology, Physiopathology and Electrocardiography: Guidelines for cardiac exercise testing. Eur Heart J 1993;14:969.)

Continued

Stress Myocardial Perfusion Scintigraphy

Stress myocardial perfusion imaging or scintigraphy is a more accurate method of diagnosing ischemic heart disease than exercise testing,[16] with a sensitivity of 80% versus 68% and a specificity of 92% versus 84%, respectively. However, stress myocardial scintigraphy adds little additional information for patients already identified as high risk through the use of conventional exercise testing. It is particularly helpful in those individuals who have equivocal exercise electrocardiographic changes, an abnormal resting ECG, suspected false-positive or false-negative exercise ECG, or submaximal exercise tolerance.

Table 12–4 Features on Exercise Electrocardiogram that are Particularly Associated with a Poor Prognosis and Indicative of Severe Disease

- Poor maximal exercise capacity (<3 of the Bruce protocol)
- ≥1-mm ST-segment depression during stage 2 or less (Bruce protocol)
- ≥2-mm ST-segment depression at any time
- Limited blood pressure response (fall or no rise from baseline)

It may also prove useful in identifying the territory of ischemia in patients with multivessel disease where selective revascularization strategies, such as culprit lesion angioplasty, are being considered. The identification of "hibernating" myocardium may be of particular benefit in patients with left ventricular dysfunction who have the most to gain from coronary revascularization.

Normal stress myocardial scintigraphy is associated with an excellent prognosis (less than 1% annual risk of a major adverse cardiac event even in patients who are known to have ischemic heart disease).[17,18] However, severe and extensive perfusion defects identify patients at a high risk of future cardiac events and a poor prognosis (Table 12–5).[19]

Table 12–5 Features on Stress Myocardial Perfusion Scintigraphy that are Particularly Associated with a Poor Prognosis and Indicative of Severe Disease

- Reversible radionuclide perfusion defect in more than one territory
- Reduced radionuclide ejection fraction with exercise
- Increased lung uptake of radionuclide

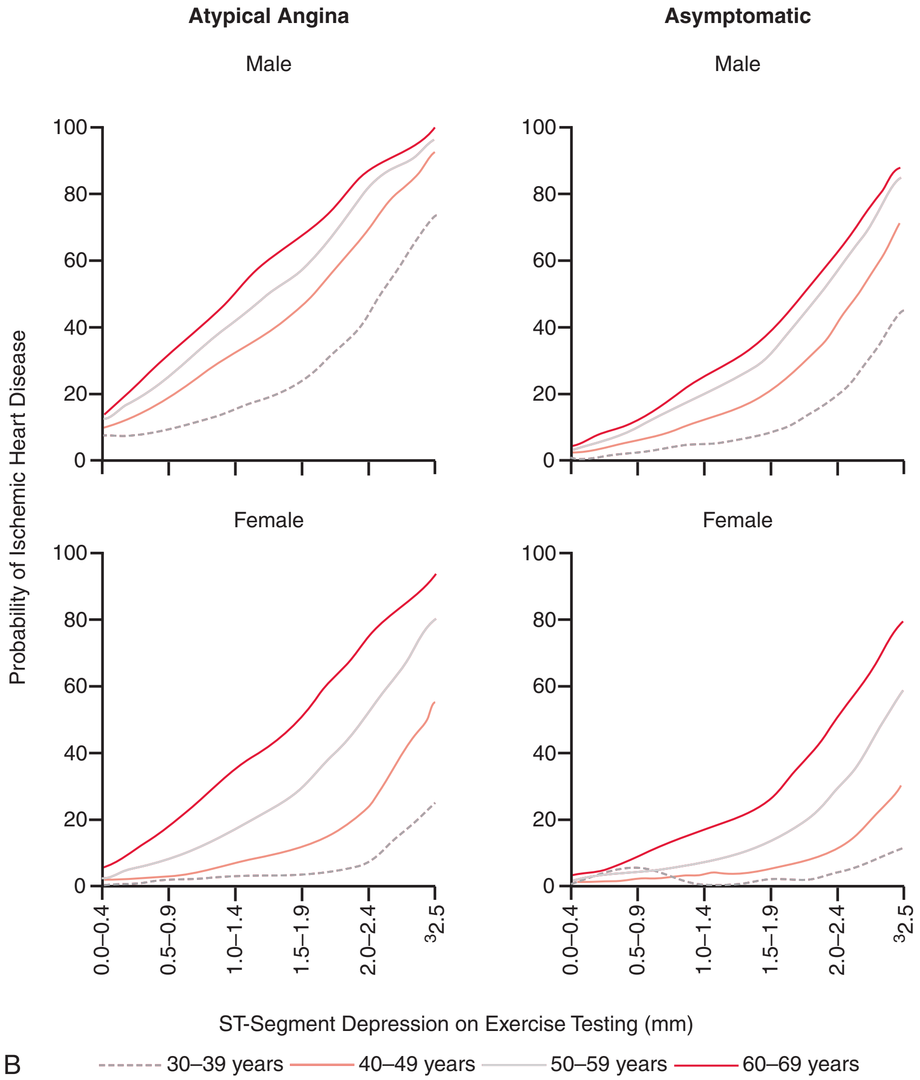

Figure 12–5, cont'd

Resting and Stress Echocardiography

Left ventricular dysfunction at rest or with exercise identifies patients with a poor prognosis.[7,20] As with myocardial scintigraphy, stress echocardiography is a sensitive and specific method of identifying patients with ischemic heart disease[21,22] and facilitates the identification of patients with left ventricular dysfunction and hibernating myocardium who would potentially benefit from coronary revascularization.

Selection and Frequency of Noninvasive Stress Testing

There are significant advantages and disadvantages with each of the three main noninvasive modalities of stress testing (Fig. 12–7 and Table 12–6). Exercise electrocardiographic testing is easily performed, has been extensively validated, and remains the noninvasive test of choice for the majority of patients. However, the sensitivity and specificity of exercise electrocardiography are reduced by intraventricular conduction defects, repolarization abnormalities, poor exercise tolerance, and concomitant cardiac medications such as digitalis.

There are no clear guidelines as to how frequently stress testing should be undertaken in patients with chronic stable angina.[23] After the initial prognostic assessment, recurrent stress testing is unlikely to be helpful unless there are new or changing symptoms or the patient has undergone, or is being considered for, an intervention such as coronary revascularization.[23]

Computed Tomography

Coronary artery calcification is an independent risk factor for coronary heart disease, with even low coronary calcium scores doubling the risk of coronary events.[24] The relative risk associated with coronary calcification is similar to that associated with established factors such as smoking, hypertension, and diabetes mellitus. Progression of coronary artery calcification is associated with a higher incidence of coronary events even in those people who are asymptomatic at the time of initial scanning.[25] Thus, the presence of coronary artery calcification is not only indicative of atheromatous plaque disease, but also its progression may correspond with cardiovascular event rates. There are scarce data on the additive prognostic information

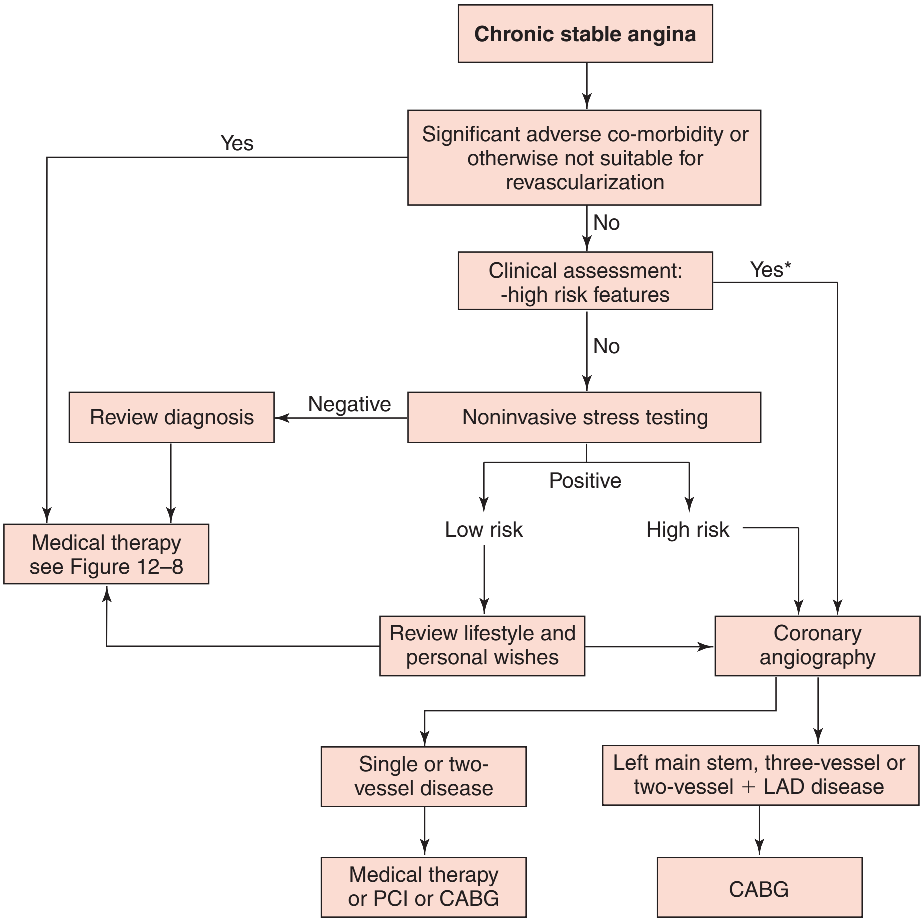

Figure 12–6 Schema for the management and treatment of patients with chronic stable angina. CABG, coronary artery bypass grafting; PCI, percutaneous coronary intervention; LAD, left anterior descending coronary artery. *Many patients with high-risk clinical features will also require noninvasive testing to further aid risk stratification.

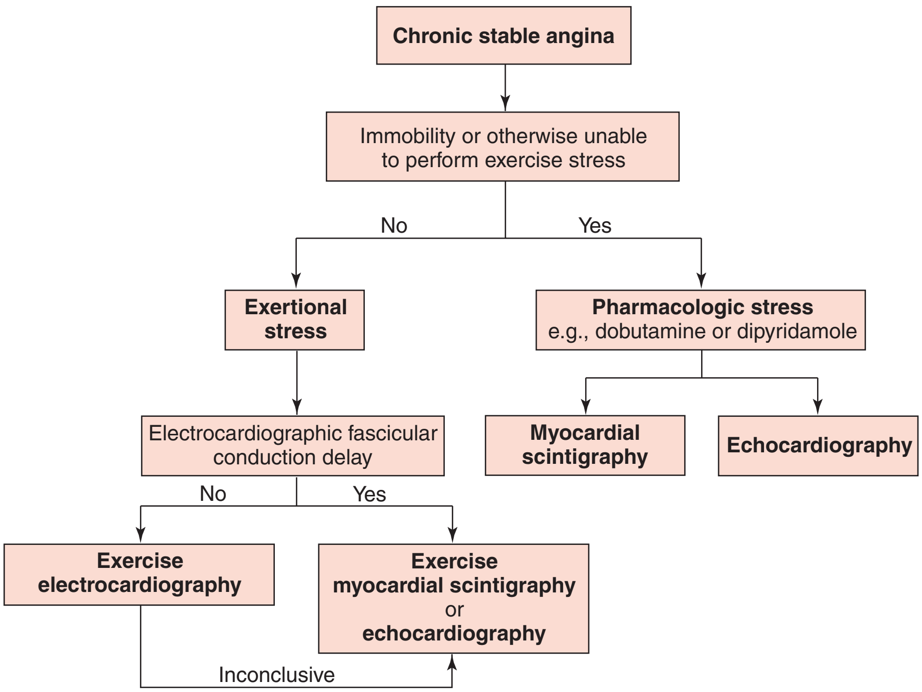

Figure 12–7 Schema for the selection of noninvasive stress testing for patients with chronic stable angina.

Table 12–6 Relative Advantages and Disadvantages of Three Main Noninvasive Stress Testing Methods

	Electrocardiography	Myocardial Perfusion Scintigraphy	Echocardiography
Technical difficulty	+	++	+++
Ease of interpretation	+	++	+++
Diagnostic sensitivity	50-80%	65-90%	65-90%
Diagnostic specificity	80-95%	90-95%	90-95%
Risk stratification	++	++	++
Identification of hibernating myocardium	–	++	+++
Identification of ischemic territory	+	++	++
Limitations	Intraventricular conduction defects and repolarization abnormalities	Radiation exposure	Limited value in patients with poor image quality
Cost	+	+++	++

in patients with stable angina, and its role is currently undefined. The ability of multidetector computed tomography scanners to reliably quantify coronary stenoses has yet to be achieved[26] but remains a promising future prospect.

Invasive Evaluation

Coronary angiography is used to aid the diagnosis and management of known or suspected coronary heart disease and is considered when either medical therapy has failed to provide effective symptomatic control or clinical and noninvasive tests suggest that the patient may be at high risk or may otherwise benefit prognostically from intervention.

Overall Assessment of Risk

A number of scoring systems[7,14,15,27-29] have been developed that incorporate both clinical characteristics and noninvasive investigations in the determination of risk. These models provide a more comprehensive assessment of risk and prognosis in patients with stable angina. Coronary angiography is appropriate in patients whose clinical characteristics or noninvasive investigations suggest they have an adverse prognosis and may therefore benefit prognostically from coronary artery bypass graft surgery (CABG) (Table 12–7; see Fig. 12–6).

The hazards of any intervention are more likely to outweigh the potential symptomatic and prognostic benefits in patients at low risk. In contrast, patients at high risk have the most to gain from interventions such as revascularization. Risk stratification is, therefore, an essential part of the initial assessment of a patient with stable angina. The main determinants of risk are patient characteristics such as age, diabetes mellitus, hypertension, and the results of clinical investigations such as exercise or other forms of stress testing, the extent of coronary disease (the number and type of vessels affected), and left ventricular function (see Figs. 12–1 to 12–3).

Table 12–7 Indications for Coronary Angiography

Severe or disabling angina. The severity of symptoms indicating the need for coronary angiography will vary depending on the patient's (and physician's) perception of the illness. However, most experts agree that patients with symptoms in Canadian Cardiovascular Society class 3 or 4, despite optimal medical therapy, may therefore benefit symptomatically from coronary artery bypass graft surgery or percutaneous coronary intervention.

Clinical indicators and noninvasive testing suggestive of adverse prognosis.

Continuing chest pain with inconclusive or negative noninvasive tests. In this context, a normal coronary angiogram can be very helpful in excluding obstructive coronary artery disease, removing uncertainty about the diagnosis, reassuring the patient, and thereby reducing their use of health care resources. This will be of particular concern when the symptoms limit the lifestyle of the patient or a diagnosis of coronary artery disease will have occupational ramifications.

THERAPEUTIC INTERVENTIONS

The treatment of patients with chronic stable angina pectoris should be directed toward both the alleviation of symptoms and an improvement in prognosis. This involves several approaches including lifestyle modification, management of risk factors, pharmacologic therapy, and coronary revascularization. All forms of intervention present certain hazards and should be instituted only if the perceived benefits, in terms of improved symptoms and prognosis, are likely to outweigh the associated risks. Such judgments are best made in the context of an overall treatment strategy that seeks to minimize the impact of the disease throughout the remainder of the patient's life. Figures 12–4 and 12–6 to 12–9 provide a general guide to the initial investigation and management of patients with chronic stable angina.

Lifestyle and Risk Factor Modifications

Lifestyle and risk factor modifications are integral parts of, and complementary to, the treatment of patients with chronic stable angina, because they may provide both symptomatic

and prognostic benefits. The benefits of exercise and exercise programs and the management of hyperlipidemia are discussed later. (The treatment and management of hypertension are discussed in Chapter 30.)

Smoking

Cigarette smoking is a major risk factor for the development of fatal and nonfatal MI.[30] Cessation of smoking is associated with major benefits, and repeated brief and supportive advice should be given to all patients.[31,32] Short-term nicotine replacement therapy should be offered to those individuals with a heavy consumption of tobacco (more than 10 cigarettes per day), because it is associated with up to a nine-fold increased likelihood of success.[33,34] The antidepressants bupropion and nortriptyline also aid long-term smoking cessation, but selective serotonin reuptake inhibitors such as fluoxetine do not.[35] This suggests that these agents produce their beneficial effects independent of an antidepressant effect. However, there appears to be no specific or effective treatment strategy to avoid relapse in smokers who have successfully quit for a short time.[36]

Dietary Intervention

Dietary intervention clearly complements the use of lipid-lowering therapy. Although a low-fat diet reduces serum cholesterol concentrations by an average of only 5%[37] even in motivated individuals,[38] dietary modification may provide additional preventive benefits, such as those obtained from a Mediterranean-type diet[39] or those high in (n-3) polyunsaturated fatty acids of fish oils.[40,41] Observational studies[42,43] and randomized trials[44] have suggested that the consumption of fruits and vegetables containing high levels of antioxidant vitamins, or supplementation with vitamin E,[45,46] is protective against the development of coronary events. However, three large-scale (n = 6000 to 30,000) multicenter randomized controlled trials[41,47,48] demonstrated that low- or high-dose vitamin E supplementation has no effect on cardiovascular outcomes. Modest alcohol consumption is associated with a reduced risk of coronary heart disease and should be limited to 21 to 28 units/week (1 unit = 8 g of absolute alcohol) for a man and 14 to 21 units/week for a woman.[49]

Obesity

There is a significant and independent association between body mass index and the risk of cardiovascular events.[50] Despite the high prevalence of obesity, there have been no interventional trials to show that weight reduction in obese patients with chronic stable angina or coronary artery disease improves symptoms or outcome. However, it is reasonable to assume that weight reduction would reduce the frequency of anginal episodes and potentially improve prognosis.

Currently escalating levels of obesity, particularly in Western societies, are associated with the development of the so-called "metabolic syndrome" characterized by obesity, insulin resistance, hypertension, and dyslipidemia. This has raised concerns about the incidence and prevalence of cardiovascular disease in the future. However, there are novel therapeutic strategies that may be able to reduce obesity and the metabolic syndrome. Cannabinoid type-1 receptor antagonism, when combined with a low-calorie diet, markedly enhances weight loss and improves many of the associated cardiovascular risk factors.[51] Its role in obese patients with coronary heart disease has yet to be established.

Diabetes Mellitus

Good glycemic control is essential in all patients with diabetes mellitus because of the reduced risk of long-term complications, including coronary artery disease. Although there are no specific trials of diabetic control in patients with chronic stable angina, primary prevention trials[52,53] and secondary prevention trials in patients after MI[54] indicate that cardiovascular morbidity and mortality rates are reduced with intensive hypoglycemic therapy regimens. Moreover, poor glycemic control at the time of presentation with MI is a poor prognostic sign.[55] Although previous studies[56] had suggested that sulfonylureas, in particular, tolbutamide, are associated with an increased risk of cardiovascular death, this was not confirmed in the U.K. Prospective Diabetes Study [UKPDS] trial.[57] The latter trial did, however, suggest that metformin should be the first-line agent of choice in overweight patients with diabetes mellitus because it is associated with a decreased risk of diabetes-related endpoints, less weight gain, and fewer hypoglycemic episodes.

Symptomatic Therapy

Cardiac Rehabilitation

Cardiac rehabilitation involves a multidisciplinary approach that addresses needs related to medical and psychosocial care, including exercise, education, secondary prevention, and vocational advice.[58] Although predominantly applied to the immediate post-MI or postoperative (after CABG) period, it is equally applicable to patients with chronic stable angina. The rehabilitation process encompasses the following three main components:

1. Explanation and understanding
2. Specific intervention, such as secondary prevention, exercise training, and psychological support
3. Long-term adaptation and education

Patients with stable angina who attend a regular exercise and rehabilitation program have less angina and may have fewer recurrent MIs, as well as better cardiorespiratory fitness and vocational status.[59,60] Exercise programs improve patient confidence and functional capacity, and although they are labor intensive, they are an efficacious and potentially cost-effective approach to the treatment of patients with stable angina (see Chapter 49).[61] Indeed, a contemporary randomized controlled trial suggested that an exercise program produced a better improvement in exercise capacity, was associated with fewer adverse cardiac events, and was more cost-effective than percutaneous coronary intervention.[62]

Pharmacologic Therapy

No single class of drug has been shown to be superior to another in the reduction of anginal episodes. However, because of the inferred secondary preventive benefits, β-blockers should be the first-line agents of choice (Fig. 12–8). Moreover,

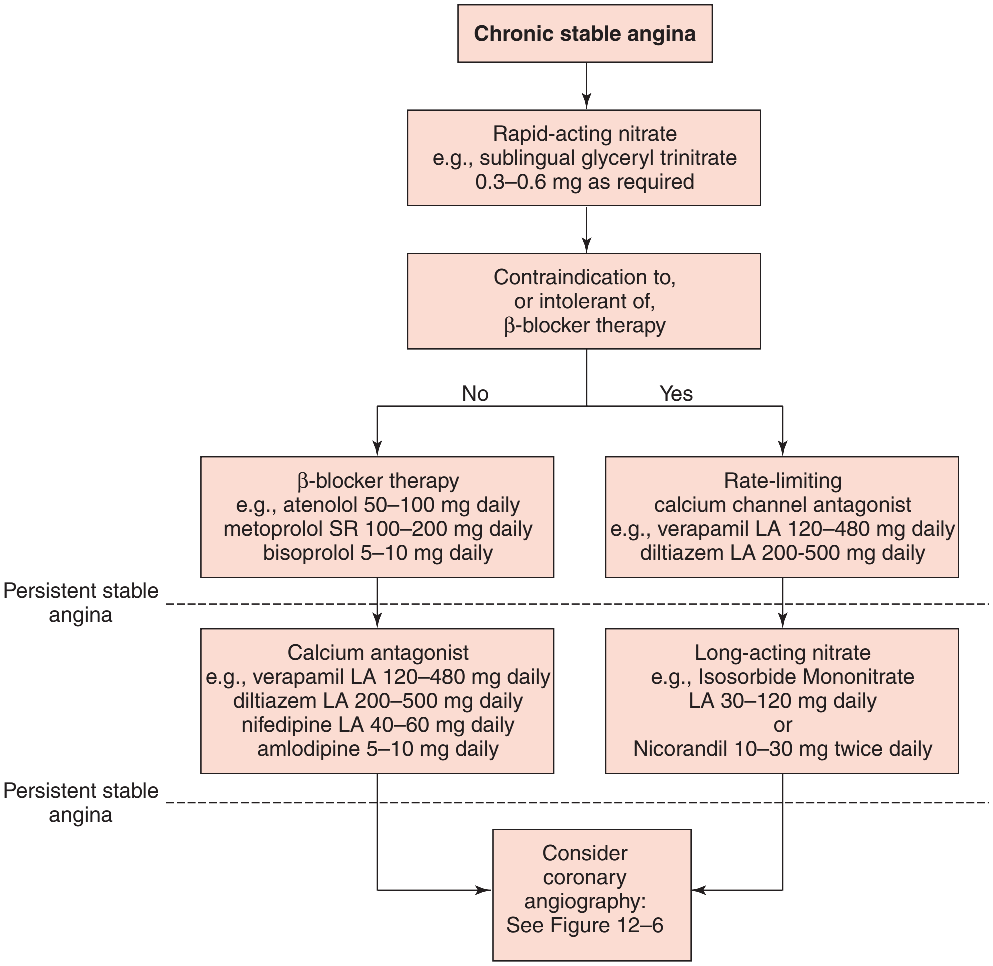

Figure 12–8 Schema for the symptomatic medical therapy management of patients with chronic stable angina. *Note:* the specific drug and dosage recommendations shown are not arranged in preferred sequence based on clinical trials and are not meant to exclude other drugs within the same class. Instead, they should be interpreted as examples of therapeutic suggestions based on the experience of the authors.

a meta-analysis suggests that β-blockers are better tolerated and may be more efficacious than calcium channel blockers in the treatment of chronic stable angina.[63]

If monotherapy does not control anginal symptoms, the introduction of a second antianginal agent provides significant but modest additional benefits (Figs. 12–8 and 12–9). The combination of β-blockade and rate-limiting calcium channel blockade may cause excessive bradycardia or heart block (see Fig. 12–8). However, this interaction is uncommon, and if there is concern, a long-acting dihydropyridine-type calcium channel blocker should also be prescribed. There is no definitive evidence that triple or quadruple antianginal therapy produces further benefit beyond dual therapy. Two large-scale (n = 5126, and 7665) randomized controlled trials of the addition of nicorandil[6] or nifedipine[5] to one or more antianginal (predominantly β-blocker) therapies demonstrated no major change in anginal symptoms, although nifedipine use was associated with a modest reduction in the need for coronary angiography (absolute reduction of 1.23% per year) and coronary artery bypass surgery (absolute reduction of 0.44% per year). Once daily and sustained-release preparations should be used whenever possible to aid compliance.

β-Blockers

β-Blockers inhibit the β-adrenergic receptors of the myocardium to produce negative chronotropism and negative inotropism of the heart. The attenuation of the heart rate response to exercise and stress reduces the myocardial oxygen demand and severity of ischemia. It also prolongs diastole, a major determinant of myocardial perfusion time. Randomized controlled trials[64,65] have demonstrated that β-blocker therapy is efficacious in reducing symptoms of angina and episodes of ischemia and in improving exercise capacity.

There is no evidence to support the suggestion that one type of β-blocker is superior to another. The so-called highly selective β-blockers, such as celiprolol or bisoprolol, or those with combined vasodilation and antioxidant properties, such as carvedilol, have no proven benefits above conventional β-blockers, such as atenolol or metoprolol. However, the secondary preventive benefits of β-blockers may be lost where agents have intrinsic sympathomimetic action,[66] and the use of such agents should, therefore, be avoided.

True side effects from β-blocker therapy are uncommon (less than 10%) but include symptoms, such as fatigue and lethargy, common complaints encountered on routine inquiry. A causative association should be established before permanent discontinuation of β-blocker therapy. Because of β-adrenergic receptor upregulation in the presence of β-blockade, patients should not be rapidly withdrawn from therapy. This can cause an acute withdrawal syndrome, and there is a suggestion that this may even precipitate acute MI.[67]

Calcium Channel Blockers

Patients who are intolerant of a β-blocker should be prescribed a rate-limiting calcium channel blocker such as diltiazem or verapamil. In the Danish Verapamil Infarction

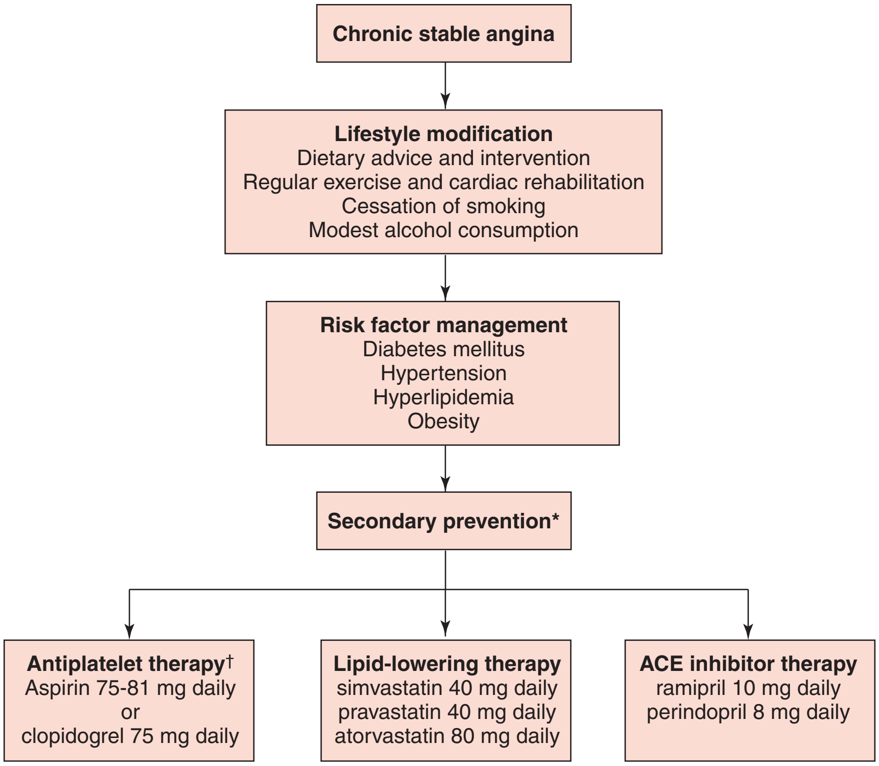

Figure 12–9 Schema for secondary prevention in patients with chronic stable angina. *If the patient is high risk, consider coronary angiography if the patient is suitable for revascularization. †Aspirin is preferred over clopidogrel as antiplatelet monotherapy. In patients who have undergone stent implantation, dual antiplatelet therapy is prescribed. See text for further discussion. *Note:* the specific drug and dosage recommendations shown are not arranged in preferred sequence based on clinical trials and are not meant to exclude other drugs within the same class. Instead, they should be interpreted as examples of therapeutic suggestions based on the experience of the authors.

Trial [DAVIT] II trial, a post-hoc analysis suggested that verapamil may be beneficial after MI in the absence of heart failure.[68] However, other calcium channel blockers[69] and classes of antianginal agents[70-72] are equally effective in relieving symptoms. The addition of nifedipine to other antianginal therapies does appear to reduce the need for further invasive investigation and revascularization.[5]

There is controversy as to whether calcium channel blockers can be used safely in patients with heart failure.[73] However, amlodipine has been shown to have a neutral effect on mortality rates in patients with heart failure and is an appropriate choice in patients with angina and significant left ventricular dysfunction.[74]

Nitrates

Nitrates were the first form of antianginal drug therapy to be discovered and used. Their mechanism of action is exerted through the release of nitric oxide either indirectly (glyceryl trinitrate) by reactions with sulfhydryl groups, such as methionine or cysteine, or directly (sodium nitroprusside) by interaction with plasma or cell membranes. The liberated nitric oxide causes endothelium-independent relaxation of vascular smooth muscle by increasing intracellular cyclic guanidine monophosphate (see Chapter 5).

Randomized controlled trials[70,75] demonstrated that nitrates are effective in reducing the frequency of anginal symptoms and in improving exercise capacity. However, as with calcium channel blockers, their use in severe aortic stenosis and hypertrophic obstructive cardiomyopathy should be avoided because of the potential to compromise coronary perfusion through peripheral vasodilatation and systemic arterial hypotension.

Acute relief of angina. Sublingual or buccal nitrates produce rapid and effective relief of acute anginal episodes. All patients should be provided with a sublingual nitrate preparation. Buccal preparations provide a more protracted release of nitrate, which is appropriate for prolonged activities that may provoke episodes of angina.

Prevention of anginal episodes. Long-acting nitrates, either oral or transdermal, provide effective relief of angina. Nitrates undergo extensive first-pass metabolism through hepatic glutathione reductases. However, topical and transdermal nitrate preparations are able to bypass such metabolism, and consequently, the overall dosage that is administered can be reduced. Alternatively, some nitrate preparations, such as isosorbide mononitrate, undergo less extensive hepatic metabolism and have better bioavailability and more prolonged action.

One of the main limitations of prophylactic nitrate use is the development of tolerance (see Chapter 5). This phenomenon requires a daily nitrate-free period,[76,77] usually nocturnal, to prevent the loss of efficacy and is a problem with all of the established nitrate preparations. The mechanism of nitrate tolerance development appears, at least in part, to be due to the depletion of sulfhydryl groups.[78] The development of *S*-nitroso-thiols potentially heralds a novel class of nitrates that may be devoid of nitrate tolerance[79] and have additional antiplatelet actions.[80]

Potassium Channel Agonists

This class of antianginal agents has vasodilatory and potential cardioprotective actions. Potassium channel openers act on the ion channels of the vascular smooth muscle cell and cardiac myocyte. Consequently, they may have a role in enhancing ischemic preconditioning[81] and improving the myocardial response to an ischemic insult.[82]

Nicorandil is the only preparation of this class in clinical use. It is effective in the treatment of angina and has both nitrate and potassium channel-opening properties. However,

there is no evidence that potassium channel openers are superior to other classes of antianginal agents, and their addition to preexisting antianginal therapy does not appear to improve symptoms.[6] The Impact of Nicorandil in Angina [IONA] trial[6] in 5126 patients with stable angina did demonstrate that nicorandil 20 mg twice daily was associated with modest 17% relative risk reduction in its primary endpoint of coronary heart disease death, nonfatal myocardial infarction, or unplanned hospitalization. The trial failed to demonstrate a difference in the secondary endpoint of coronary heart disease death and myocardial infarction.

Coronary Revascularization

Both CABG and percutaneous coronary intervention (PCI) carry measurable early morbidity and mortality risks that exceeds the early risks of medical therapy. As indicated, all interventions should be instituted only if the perceived benefits, in terms of improved symptoms and prognosis, are likely to outweigh the associated risks. This is particularly important when the therapy is targeted at symptomatic rather than prognostic benefits, such as with PCI or CABG for one-vessel disease.

Selection of the appropriateness and the type of revascularization procedure will be heavily influenced by technical aspects of the coronary anatomy, as well as by factors such as comorbidity and patient preference. What is considered to be an acceptable level of symptoms, optimal medical therapy, and tolerable drug side effects may vary greatly from patient to patient. Thus, the need for, and type of, coronary revascularization should take into account both objective clinical criteria and the patient's symptoms (see Chapter 8).

Several factors must also be considered when evaluating the applicability and evidence of the clinical usefulness of coronary revascularization strategies. First, the major randomized trials are based on highly selected patient groups and may not reflect the broad mix of patients who present to the clinic. For example, the Angioplasty Compared with MEdicine [ACME] trial[83] recruited only 212 patients out of the nearly 5000 who were screened. Second, most trials have not exclusively selected patients with chronic stable angina pectoris. Third, many datasets reported in the literature are outdated. Medical therapy has improved and become more effective. Similarly, the surgical results do not take account of the improvements in techniques and the increasing use of arterial conduits (Fig. 12–10). Indeed, the initial failure and restenosis rate in PCI has been reduced by the introduction of coronary artery stent deployment (Fig. 12–11), drug-eluting stents, and adjuvant therapy with antiplatelet agents.[84]

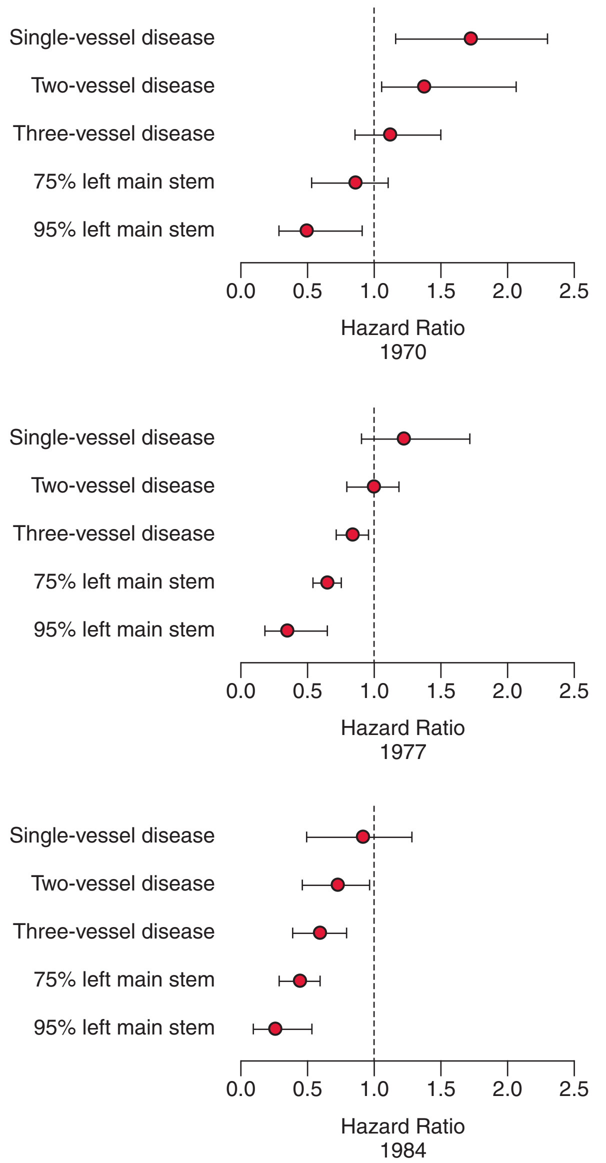

Figure 12–10 Improvements in survival with coronary artery bypass graft surgery (to left of vertical dashed lines) during a 14-year period. (Data from Califf RM, Harrell FE, Lee KL, et al: The evolution of medical and surgical therapy for coronary artery disease: a 15-year perspective. JAMA 1989;261:2077.)

Percutaneous Coronary Intervention

Complications

The most common serious complication of PCI is acute occlusion of the dilated vessel due to dissection or thrombosis. Other complications include vascular damage; thromboembolism, including stroke; and hemorrhage due to anticoagulant therapy. Although the risks are greatest with acute coronary syndromes,[85,86] elective percutaneous coronary intervention is associated with overall angiographic success rates of 96% to 99%, with transmural myocardial infarction rates of 1% to 3%, emergency coronary bypass surgery rates of 0.2% to 3%, and unadjusted in-hospital mortality rates of 0.5% to 1.4%.[87]

The reported risk of angiographic restenosis for isolated balloon angioplasty is 25% to 40%.[88-91] Restenosis occurs predominantly within the first 3 to 6 months,[89,90] does not always lead to recurrent symptoms, and has been dramatically reduced by the widespread use of intracoronary stents,[88,92-96] particularly drug-eluting stents. Current rates of restenosis with drug-eluting stents are 5% to 10%.[97]

The success and complication rate of PCI are influenced by many factors, including age, gender, clinical presentation, left ventricular function, comorbidity (e.g., diabetes mellitus), and the experience of the operator.[86,98] However, the most important determinant of outcome is the nature of the target

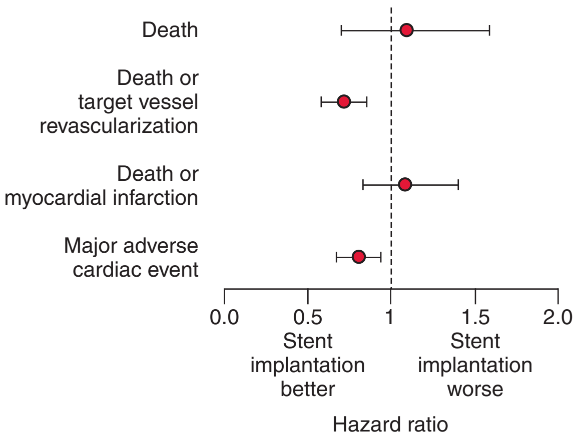

Figure 12–11 Improvements in 1-year clinical outcome with the introduction of coronary stenting. (Data from Rankin JM, Spinelli JJ, Carere RG, et al: Improved clinical outcome after widespread use of coronary artery stenting in Canada. N Engl J Med 1999;341:1957.)

lesion. A short, discrete, soft lesion on a straight segment of artery that does not compromise a major branch is ideal for PCI. Lesions that are less suitable for PCI include chronic total occlusions, long lesions, calcifications, lesions that lie on tortuous segments or flexures, and lesions that involve branch vessels. PCI has a high success rate and low complication rate for ideal lesions but a low success rate and high complication rate for complex lesions.

Indications: PCI versus Medical Treatment

The first randomized controlled trial to assess the usefulness of PCI in comparison with medical therapy was the ACME trial.[83] This study recruited patients with one-vessel disease, the majority of whom (>90%) had stable angina pectoris, and demonstrated that PCI is associated with superior subjective and objective improvements in anginal symptoms at 6 months.[83,99] However, there was concern that PCI was associated with a higher incidence of complications, particularly recurrent revascularization procedures.

The subsequent Randomised Intervention Treatment of Angina [RITA-2] trial[100] was a larger (n = 1018) and more powerful randomized controlled trial that was designed to compare the effects of PCI with medical therapy in patients with angina and one-vessel (60%) or multivessel (40%) disease. The study population did, however, include patients who had quiescent angina with no symptoms (20%) or recent (7 to 90 days before randomization) unstable angina (10%). Consistent with the ACME trial,[83] an initial strategy of PCI was associated with significantly less angina for at least 2 years after the procedure compared with medical treatment. This reduction in anginal symptoms was associated with a diminished requirement for antianginal drug therapy, an increase in exercise capacity, and an overall improvement in quality of life.[100,101] However, reflecting the low-risk population of patients recruited into this trial, PCI was associated with nearly twice the risk of death or nonfatal MI (6.3% versus 3.3% at 2.7 years, $P = 0.02$), which occurred predominantly in the first 3 months after randomization. It should also be noted that one fourth of patients randomized to medical treatment required a revascularization procedure during follow-up owing to worsening symptoms.

The symptomatic benefits of PCI in the RITA-2 trial[100] appeared to be most marked in the patients with severe symptoms or limited exercise tolerance. It may, therefore, be necessary to accept a small initial procedure-related hazard from PCI to gain relief from severe or limiting anginal symptoms. However, improved imaging and stent technologies combined with better antiplatelet therapies, such as the thienopyridines and glycoprotein IIb/IIIa receptor antagonists, mean that the hazards identified in RITA-2[100] have been overestimated in the current era. Thus, PCI is an appropriate intervention in chronic stable angina patients with suitable coronary anatomy who have chronic stable angina with limiting symptoms despite medical treatment (see Fig. 12–6).

PCI versus CABG

A meta-analysis[102] of eight large randomized controlled trials that compared PCI (n = 1710) with CABG (n = 1661) in patients with predominantly stable angina (80%) has shown no significant difference in survival between the two revascularization strategies during a mean follow-up of 2.7 years. There is, however, a significant difference in the subsequent need for additional revascularization, with 17.8% of patients randomized to PCI requiring CABG within 1 year and about 2% per year requiring CABG in subsequent years. The prevalence of angina at 1 year was considerably higher in the PCI group (1.5- to 2-fold), but at 3 years, this difference was no longer significant.[102]

The Bypass Angioplasty Revascularization Investigation [BARI] trial[103] was published after the meta-analysis by Pocock and colleagues[102] and is the largest study to compare PCI with CABG, although only 40% of patients recruited into this trial had stable angina. This trial also showed no significant difference in survival or risk of MI between PCI and CABG patients; however, PCI was again associated with a higher rate of subsequent revascularization procedures (8% for CABG versus 54% for PCI at 5 years). This excess of additional procedures for PCI was again seen predominantly in the first year. However, in the Arterial Revascularisation Therapy Study [ARTS][104] and Stent or Surgery [SOS, 2002] trials,[105] the introduction of elective coronary artery stenting reduced the apparent need for recurrent revascularization procedures in patients with multivessel disease (4% to 6% for CABG versus 17% to 21% for PCI at 1 to 2 years). The further impact of drug-eluting stents on recurrent revascularization procedures after PCI has not been assessed in comparison with a strategy of CABG.

The Duke University data base (n = 9263) describes a single-center prospective experience of the outcomes in patients with ischemic heart disease (20% of patients had stable angina) who were managed with medical therapy, PCI, or CABG. These data suggested that patients with one-vessel disease or two-vessel disease without involvement of the proximal left anterior descending coronary artery (LAD) experience better clinical outcomes with PCI than with CABG.[106,107] This contrasts with the findings of the Pocock and colleagues[102] meta-analysis, where the combined endpoint of death or MI in one-vessel disease appeared to be less frequent with CABG than with PCI (4.5% versus 7.2%). However, the subgroup analysis reported by Pocock and colleagues encompassed only

three trials with small numbers ($n = 350$ for each group), and the authors question the reliability of the finding.[106] In contrast to the Duke University data base, the patients in these randomized trials were highly selected populations: for example, the RITA trial[108] recruited only 3% of patients undergoing an angiogram.

Therefore, it would appear that PCI is an appropriate alternative to CABG in patients with symptom-limiting chronic stable angina despite medical treatment who have suitable one-vessel disease or two-vessel disease without a significant proximal LAD stenosis.

Culprit Lesion PCI

When the main objective of revascularization is the relief of angina, it may be advisable to consider PCI of the lesion that is believed to be responsible for the patient's symptoms, even if there is evidence of multivessel disease that might otherwise be treated with CABG. This strategy, known as culprit lesion PCI, is often appropriate in symptomatic patients with multivessel coronary artery disease who have a single exceptionally severe stenosis and many minor lesions or in those patients who are unsuitable for CABG owing to comorbid conditions such as cerebrovascular disease or chronic obstructive airway disease.[109] Culprit lesion PCI is also a reasonable option in situations where surgical revascularization with CABG would be incomplete and, therefore, may not confer prognostic benefit.

PCI After CABG

Five years after undergoing CABG, 50% of patients will have redeveloped angina,[23] and by 12 years, 30% will have undergone repeat revascularization.[110] Repeat CABG is associated with a higher risk and a lower likelihood of benefit than the initial intervention. In an analysis of 632 nonrandomized patients with previous CABG who required either elective repeat CABG or PCI, complete revascularization was achieved in 38% of patients who underwent PCI compared with 92% of patients who underwent CABG. However, complications were significantly lower with PCI (0.3% versus 7.3%), and survival was similar at 1 and 6 years of follow-up. Both procedures resulted in similar event-free survival from death, MI, and angina, but by 6 years, further revascularization with either repeat PCI or CABG was significantly higher with PCI (64% versus 8%).[111]

These findings were confirmed in a larger cohort of 4174 patients who underwent coronary revascularization (nonrandomized PCI or CABG) after previous CABG.[112] Repeat CABG was associated with a higher in-hospital mortality rate (6.8%) than PCI (1.2%), but mortality rates were similar at 1, 5, and 10 years. PCI was again associated with an increased risk of recurrent angina and additional procedures.

When technically feasible, we prefer an initial strategy of PCI rather than repeat CABG in chronic stable angina patients with limiting angina despite previous CABG and medical therapy.

Stents

Intracoronary stents were initially used for the management of serious complications arising from PCI such as acute or threatened vessel occlusion, so-called *bail-out stent implantation*. This provided an extremely useful way of maintaining vessel patency and led to a reduction in the need for emergency CABG after PCI.[113] Observational studies[96,113-115] and initial randomized controlled trials have confirmed the clear usefulness of the technique in the management of acute vessel closure.

Several randomized controlled trials assessed the efficacy of elective intracoronary stenting. Some of the studies have methodologic limitations such as control patients who did not receive matched anticoagulation regimens (the STent REStenosis Study [STRESS] trial)[88] or investigators who were not fully blinded (the BElgian NEtherlands STENT [BENESTENT] and Stenting In Chronic Coronary Occlusion [SICCO] trials).[92,116,117] However, all trials report consistent findings, with elective stenting being associated with improved procedural and clinical outcomes and a reduction in the need for subsequent revascularization procedures. The clearest evidence has come from PCI procedures for higher-risk lesions, namely chronically occluded arteries,[117-119] saphenous vein grafts,[120] proximal LAD stenoses,[95] and restenosis after prior PCI.[121,122] Stent implantation is also appropriate when conventional PCI has produced a suboptimal result.[93]

In the BENESTENT study,[92] the effect of elective stenting of all lesions was compared with the use of PCI alone in patients with stable angina and a single new lesion. There were no procedure-related deaths in this trial, and stenting was associated with improved clinical and angiographic outcomes. The subsequent BENESTENT II study[123] included patients with unstable angina (40%) and was able to confirm the benefits of elective stent implantation using heparin-coated stents. However, a more selective approach of stent implantation for high-risk lesions or suboptimal angiographic results may confer similar benefits and be more appropriate.[124]

Observational studies[96,113,125] and randomized controlled trials[88,92,116,126] indicate that after stent implantation, patients have less restenosis and greater event-free survival from MI and repeated coronary intervention. Subsequent to the widespread use of stents in Canada, evidence of improved clinical outcome, particularly a reduced need for recurrent coronary intervention, was observed (see Fig. 12–11).[96]

Coated stents have become available wherein agents are impregnated into a polymer coating (see Chapter 7). One of the first to be employed was a heparin-coated stent. This was used to reduce the incidence of stent thrombosis and restenosis. However, these heparin-coated stents had limited benefits above bare metal stents. There has been major interest in the use of drug-eluting stents that contain antiproliferative agents. Sirolimus is a macrolide antibiotic with antifungal, immunosuppressive, and antimitotic properties that has been used in the prevention of renal transplant rejection. Sirolimus-coated stents are associated with a dramatic reduction in the incidence of in-stent restenosis, with failure of target vessel revascularization falling from 21.0% to 8.6% in the SIRIUS study of 1058 patients with coronary heart disease.[97] Paclitaxel is a microtubule-stabilizing agent with potent antitumor activity that has also been successfully used in stent coatings with similar reductions of in-stent restenosis.

Antiplatelet Therapy

All patients with coronary artery disease should be maintained on aspirin therapy (see later) (see Fig. 12–9).[127] Aspirin therapy is associated with a 53% reduction in the rate of vas-

cular occlusion after PCI (2.7% versus 5.5%).[127] The combination of ticlopidine (250 mg twice daily) and aspirin (100 mg twice daily) compared with conventional anticoagulant therapy reduces both cardiac events and the associated hemorrhagic and vascular complications after PCI and stent deployment.[128] Indeed, the combination of aspirin and ticlopidine is supe-rior to the use of aspirin either alone or in combination with warfarin.[129] Observational data[130] indicate that clopidogrel (75 mg/day) is as efficacious as ticlopidine in the prevention of stent thrombosis and is now the first-line agent of choice.[131]

More potent platelet antagonists have become available that inhibit the platelet glycoprotein IIb/IIIa receptors (see Chapters 5 and 10). A meta-analysis[132] of 16 randomized controlled trials incorporating 32,135 patients confirms the modest beneficial effects of platelet glycoprotein IIb/IIIa antagonists in patients during PCI or acute coronary syndromes. The ISAR-REACT trial has brought into question the role of glycoprotein IIb/IIIa receptor antagonists in elective percutaneous coronary intervention.[133] When all patients are pretreated with a large oral loading dose (600 mg) of clopidogrel, there appears to be no additional benefit of a glycoprotein IIb/IIIa receptor antagonist, although appropriately powered trials with a broad spectrum of patients at different degrees of risk of events need to be performed.

Coronary Artery Bypass Graft Surgery

Complications

When contemplating revascularization surgery in patients with chronic stable angina, it should be recalled that CABG is a safe operation with an elective surgical mortality rate frequently reported at around 2% to 4%, depending on the case mix.[134] Various factors influence surgical mortality rates, including age, gender, degree of left ventricular impairment, and the presence of other comorbid conditions, such as diabetes mellitus, obesity, and hypertension (Fig. 12–12).[134]

Indications. CABG Versus Medical Treatment

The three major randomized controlled trials that compared CABG with medical therapy are the Coronary Artery Surgery Study [CASS],[135] the Veterans Administration [VA] Cooperative Study,[11,136] and the European Coronary Surgery Study [ECSS].[12,137] These studies form the basis of the meta-analysis by Yusuf and colleagues[138] that compares CABG with medical therapy in patients with chronic stable angina.

In comparison with medical therapy, CABG significantly improves symptoms of angina and exercise capacity and reduces the need for antianginal therapy.[135] After CABG, more than 70% of patients are free of angina at 1 year and 50% are free at 5 years.[135,137] Patients experience a better quality of life after CABG[135,139,140] and report less limitation in physical activity.[135] Seventy-three percent of patients are working 1 year after CABG.[140]

Therefore, CABG is an appropriate intervention in patients who have suitable coronary anatomy with chronic stable and symptom-limiting angina despite medical treatment (see additional discussion in Chapter 8).

Arterial Conduits

As a consequence of graft vasculopathy, saphenous vein bypass grafts have an accelerated failure rate that is particularly evident beyond the fifth year. Arterial conduits are being used increasingly in an attempt to improve graft survival. The internal mammary arteries are the principal conduits to have been assessed, although other conduits, such as the radial and gastroepiploic arteries, may also be used (Chapter 8).

Fifteen years after CABG, 88% of left internal mammary artery grafts remain patent compared with only 32% of saphenous vein grafts.[141] Observational and quasi-experimental studies have shown that this improved patency rate is associated with better long-term survival rates and a reduction in the risk of angina, hospitalization, MI, and repeat operation.[142-144] Overall, patients who undergo CABG with saphenous vein

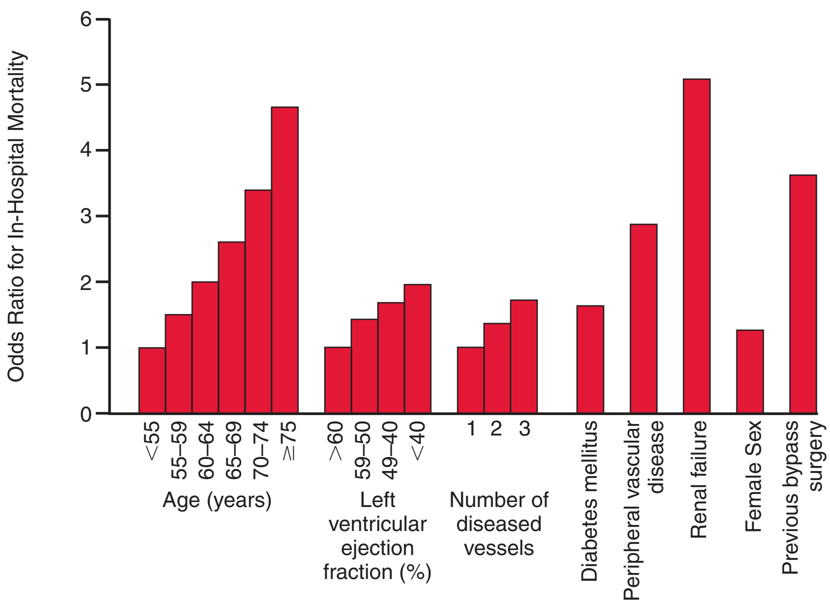

Figure 12–12 Odds ratio for in-hospital mortality rate for a selection of patient characteristics. Patients with chronic stable angina comprise 40% of the study population. (Data from O'Connor GT, Morton JR, Diehl MJ, for the Northern New England Cardiovascular Disease Study Group: Differences between men and women in hospital mortality associated with coronary artery bypass graft surgery. Circulation 1993;88:2104.)

grafts have only a 1.6-fold greater risk of death over 10 years compared with those who receive an internal mammary artery graft.[142] Given the chronic nature of ischemic heart disease, where technically feasible, CABG surgery should incorporate the use of arterial conduits such as one or both of the internal mammary arteries.

Secondary Prevention

Many approaches have been taken to improve the prognosis of patients with ischemic heart disease (see Fig. 12–9). Some therapeutic interventions are associated with marked benefits, whereas others remain unproven or have neutral effects (Fig. 12–13). However, as in the case of PCI, it may be necessary to accept a small initial risk to improve the patient's symptoms and quality of life. The side effects of therapy, such as angiotensin-converting enzyme (ACE) inhibitor-induced cough, may limit the use of agents with proven prognostic benefits.

Cardiac Rehabilitation

The majority of randomized controlled trials of cardiac rehabilitation have been conducted in patients who have sustained a recent MI and indicate that significant morbidity and mortality benefits can be achieved.[145] Although the benefits appear to be most prominent in the first 2 years, the secondary preventive effects appear to be sustained during a 10-year period.[146] Although these benefits have not been definitively demonstrated in populations of patients with chronic stable angina in the absence of MI, the referral of such patients to a cardiac rehabilitation program is appropriate (see Chapter 49).

Antiplatelet Therapy

Although aspirin is a weak inhibitor of platelet aggregation, it is a simple and effective treatment in patients with chronic stable angina. The Antithrombotic Trialists' Collaboration performed a meta-analysis that demonstrated a significant morbidity and mortality benefit (33% relative risk reduction) with long-term aspirin therapy in patients with chronic stable angina,[127] especially in those who have undergone coronary revascularization (Fig. 12–14).[127] Because of this proven reduction in the risk of death and MI, all patients with stable angina pectoris should be maintained on regular aspirin therapy. Similar benefits of aspirin therapy are seen at all doses of ≥75 mg daily whereas bleeding risks increase in a dose-dependent manner. It would appear that aspirin 75–81 mg daily is the preferred dose for long-term secondary prevention. If there is concern regarding the risk of peptic ulceration and gastrointestinal bleeding, then co-administration of a proton pump inhibitor is appropriate.[147]

The weak antiplatelet action of aspirin has led to the search for other, more potent antiplatelet agents (see Chapter 5). In the CAPRIE trial,[148] long-term clopidogrel treatment (75 mg/day) is at least as efficacious as aspirin in the preven-

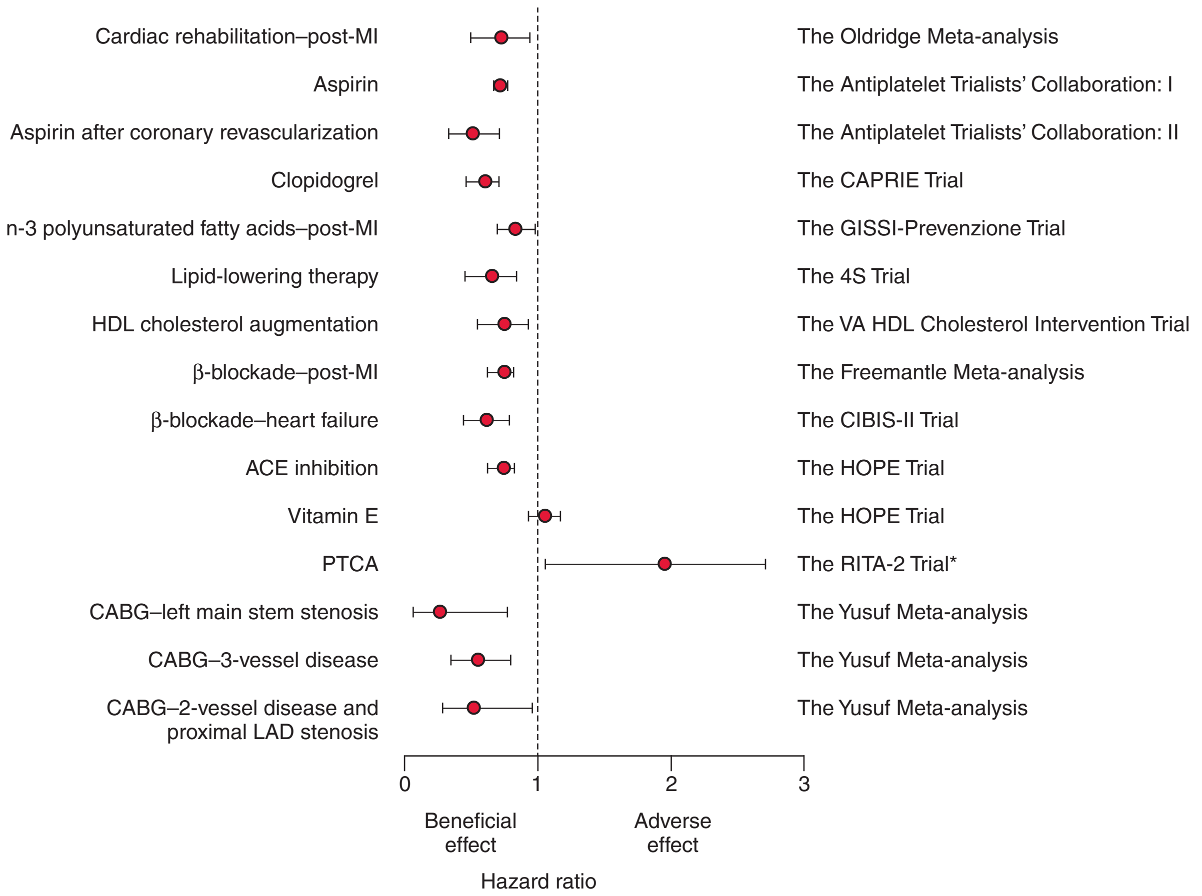

Figure 12–13 Proportionate benefits of a range of potential secondary preventive therapies. *The RITA-2 Trial predominantly recruited patients with a low cardiovascular risk. (From the RITA-2 Trial Participants: Coronary angioplasty versus medical therapy for angina: The second Randomized Intervention Treatment of Angina (RITA-2) Trial. Lancet 1997;350:461.)

tion of ischemic stroke, MI, or vascular death in patients with atherosclerotic vascular disease. Although the overall secondary preventive benefits of clopidogrel statistically exceeded those of aspirin, the relative benefits were modest (relative risk reduction, 8.7%; $P = 0.04$) and, due to significant study population heterogeneity ($P = 0.04$), may not confer superior benefit to aspirin in patients with stable ischemic heart disease. Clopidogrel is beneficial when used in combination with aspirin, in patients with acute UA/NSTEMI (see Chapter 10). Clopidogrel is indicated as an alternative to aspirin, particularly in patients with aspirin sensitivity. Combination aspirin and clopidogrel therapy is of minimal benefit in patients with chronic stable angina and cannot be recommended for long-term secondary prevention.

Potent platelet antagonists have become available that inhibit the final common pathway of platelet aggregation, the platelet glycoprotein IIb/IIIa receptor. Trials of oral non-peptidic antagonists of the IIb/IIIa receptor in patients with a recent acute coronary syndrome have been disappointing and were associated with an increase in mortality.[149,150] The role of such agents in patients with chronic stable angina has not been directly assessed, but they are unlikely to have significant secondary preventive benefits and may cause harm.

Lipid-Lowering Therapy

Serum cholesterol concentrations should be assessed in all patients with chronic stable angina to detect hypercholesterolemia and should be treated with a hydroxy-3-methyl glutaryl coenzyme A reductase inhibitor or "statin" irrespective of the serum cholesterol concentration (see Chapter 26). There have been several large-scale randomized controlled trials to address the issue of lipid-lowering therapy in patients with ischemic heart disease. The Scandinavian Simvastatin Survival Study [4S] trial[151] was the first to demonstrate a significant improvement (relative risk reduction, 30%) in mortality rates with the use of statins in patients with ischemic heart disease and a serum cholesterol concentration of more than 210 mg/dL (more than 5.5 mmol/L). These mortality benefits have been demonstrated with both simvastatin and pravastatin,[152] and the goal of therapy appears to be suppression of the serum total cholesterol concentration to at least below 190 mg/dL (below 5.0 mmol/L). The Cholesterol and Recurrent Events [CARE] study[152] has, in addition, suggested that patients with average cholesterol concentrations (low density lipoprotein [LDL] cholesterol, 120 to 150 mg/dL; 3.2 to 3.9 mmol/L) should also be considered for lipid-lowering therapy because it is associated with a similar 26% relative risk reduction in future adverse cardiac events. However, the absolute risk of a subsequent cardiac event is proportionately lower in patients with such normal concentrations, especially in patients with only chronic stable angina. In contrast, more aggressive lipid lowering appears to have substantial additional benefits in patients who have undergone saphenous vein bypass grafting,[153] and under such circumstances, target LDL cholesterol concentrations should be below 100 mg/dL (below 2.6 mmol/L).

The 4S trial[151] has been the only large-scale mortality study to specifically recruit patients with chronic stable angina. However, the benefits of lipid-lowering therapy in chronic stable angina were also demonstrated in the Atorvastatin VErsus Revascularization Treatment [AVERT] study.[154] During an 18-month follow-up period, this trial was able to demonstrate that in patients with chronic stable angina, atorvastatin reduced the number of acute ischemic

events—hospitalization for worsening angina or coronary revascularization procedures—in comparison with intervention with PCI (13% versus 21%, respectively). However, PCI was associated with a greater improvement in chronic anginal symptoms than atorvastatin (54% versus 41%, respectively), and a large amount of the effect seen is likely to reflect the RITA-2 trial observations[100] that PCI improves chronic symptoms at the cost of a small but significant increase in short-term ischemic events.

In the initial secondary prevention trials, patients were predominantly recruited if serum total cholesterol concentrations were above a certain threshold—usually around 190 mg/dL. There appeared to be a threshold effect in the CARE trial[152] that suggested there was no merit in reducing serum LDL cholesterol concentrations to below 120 mg/dL. The subsequent Heart Protection Study[155] has now definitively established that all patients with coronary heart disease should receive statin therapy: it is the overall absolute risk that is important rather than the cholesterol concentration per se. If a patient is at high-risk, he or she will benefit from cholesterol reduction irrespective of their cholesterol concentration (i.e., there does *not* appear to be a threshold effect for the benefits of statin therapy). For example, in the Heart Protection Study,[155] patients with a total cholesterol concentration of less than 190 mg/dL had a 5-year event rate of 22.1% that was reduced to 16.9% by simvastatin 40 mg daily. Thus, a patient with chronic stable angina, diabetes mellitus, or peripheral vascular disease will merit having statin therapy even if his or her total cholesterol concentration is 136 mg/dL. A meta-analysis[156] of 14 major statin trials incorporating 90,056 individuals has reaffirmed these benefits and suggests that event reduction is proportional to LDL cholesterol reduction (Fig. 12–15).

How low should the serum cholesterol concentration be reduced in patients with chronic stable angina? The PROVE-IT[157] and TNT[158] trials have assessed, respectively, whether more intensive lipid-lowering therapy is associated with better outcomes in patients with recent unstable or chronic stable coronary heart disease. Both trials show a consistent benefit in reducing serum LDL cholesterol concentrations below contemporary guidelines (to a mean of 62 to 77 mg/dL). In the TNT trial,[158] 30 patients treated with atorvastatin 80 mg daily for 5 years will avoid 1 major cardiovascular event in comparison with those receiving atorvastatin 10 mg daily. The IDEAL trial compared atorvastatin 80 mg daily with simvastatin 20 mg daily as secondary prevention in patients with a previous MI.[158a] The achieved LDL cholesterol was 81 mg/dL compared with 104 mg/dL in the simvastatin group. The composite primary endpoint of coronary death, nonfatal MI, or resuscitated cardiac arrest tended to be lower in the high-dose atorvastatin group (HR 0.89; 0.78 to 1.01, $P = 0.07$); nonfatal MIs were significantly reduced with high-dose atorvastatin (HR 0.83; 0.71 to 0.98; $P = 0.02$) over a median follow-up of 4.8 years.

Other classes of drugs, such as fibrates, also lower serum lipid concentrations, but although it is inferred, they have not been shown clearly to reduce mortality rates in randomized controlled trials. One exception to this is the Veterans Affairs trial of gemfibrozil, which demonstrated significant secondary preventive benefits of elevating reduced high-density lipoprotein (HDL) cholesterol concentrations.[159] Patients with ischemic heart disease, including patients with chronic stable angina, and a normal LDL cholesterol concentration (140 mg/dL or less) but a reduced HDL cholesterol concentration (40 mg/dL or less) benefited from 1.2 g/day gemfibrozil, which elevated HDL cholesterol concentrations by 6% and reduced total cholesterol and triglyceride concentrations by 4% and 31%, respectively, without altering LDL cholesterol concentrations. Fibrates should, therefore, be considered in patients with normal LDL but low HDL cholesterol concentrations.

β-Blockers

There have been no randomized controlled trials to demonstrate that β-blocker therapy improves survival in patients with chronic stable angina. However, post-MI,[66,160] hypertension, and case-control[161] studies have shown that patients maintained on β-blockers are less likely to have a vascular event and have a reduced mortality rate if they subsequently experience an MI. For these reasons, we believe β-blockers should be the first-line agents of choice for patients with chronic stable angina. Furthermore, despite claims to the contrary, hypertension[162] and angina[63,65] trials indicate that β-blockers are better tolerated and have fewer side effects than calcium channel antagonists. Concerns that β-blocker therapy is associated with reduced peripheral perfusion, due to unopposed α-adrenergic vasoconstriction and blockade of β_2 vascular receptors, are unfounded,[163] even in patients with peripheral vascular disease. β-Blockers may have significant secondary preventive benefits in patients with peripheral vascular disease—as suggested by the marked reductions in perioperative mortality and MI rates in such patients undergoing major vascular surgery.[164]

Because of the common risk factor of smoking, many patients with angina have chronic obstructive pulmonary disease and are denied β-blocker therapy owing to the concern of provoking bronchospasm. However, there is a large body of observation data demonstrating that patients with obstructive pulmonary disease derive similar mortality benefits (40% relative risk reduction) after MI with β-blocker therapy.[160] Therefore, such patients should be given a trial of β-blockade because the majority tolerate therapy well. If there is genuine concern of clinically significant reversible bronchospasm, formal spirometry in the presence and absence of a β_2-agonist, such as 5 mg nebulized salbutamol, should be performed.

Patients with chronic stable angina and coexistent heart failure are particularly at risk and should also be given β-blocker therapy as the agent of choice. There have been several large-scale randomized controlled trials that demonstrated major mortality and morbidity benefits in patients with mild to severe heart failure[165,166] who were maintained on β-blocker therapy. Although cautious dose up-titration and close clinical observation for cardiac decompensation are necessary, the withdrawal rates of patients with heart failure from β-blocker therapy are modest (15%) and equivalent to those for placebo.[166] Moreover, rates of rehospitalization are reduced and symptoms of heart failure are improved with β-blocker therapy.[166]

Angiotensin-Converting Enzyme Inhibition

The major morbidity and mortality benefits of ACE inhibitor therapy were first demonstrated in patients with heart failure.[167,168] These benefits are likely to reflect an anti-ischemic action of ACE inhibition, particularly given the

evidence from the Heart Outcomes Prevention Evaluation [HOPE][169] and the EURopean trial On reduction of cardiac events with Perindopril in stable coronary Artery disease [EUROPA] studies.[170] The HOPE study[169] was a large-scale randomized controlled trial of 9297 high-risk patients with vascular disease (55% with chronic stable angina) in the absence of documented heart failure. During the 4.5 years of follow-up, ramipril was associated with reductions in all-cause mortality, MI, and stroke.[169] These beneficial effects appeared to be independent of the associated reductions in blood pressure and were particularly marked in patients with diabetes mellitus.[171] These findings have been subsequently confirmed in the EUROPA trial of 13,655 patients with stable coronary heart disease.[170] Perindopril 8 mg daily was associated with a 20% relative risk reduction in the likelihood of cardiovascular death, myocardial infarction, or cardiac arrest: 50 patients needed to be treated for 4 years to avoid one event. The Prevention of Events with Angiotensin Converting Enzyme inhibition [PEACE] trial[172] contrasts to the HOPE[169] and EUROPA[170] trials because it failed to demonstrate a benefit of trandolapril in 8,290 patients with stable coronary heart disease. However, the event rate in this trial was unexpectedly low and was below the rate in the treatment arms of both the HOPE and EUROPA trials.[169,170]

All patients with chronic stable angina with a predicted 10-year event rate >15% should be maintained on chronic ACE inhibitor therapy because of the associated major secondary preventive benefits.

Coronary Revascularization

There have been no randomized controlled trials to demonstrate that PCI improves long-term prognosis and survival in patients with chronic stable angina. Indeed, several studies indicated that PCI is associated with a worse medium-term prognosis than medical therapy.[100,154] In contrast, in selected groups, CABG is associated with significant reductions in mortality rates compared with medical therapy. Comparisons of the prognostic benefits of PCI and CABG demonstrated no statistically significant differences between the two approaches,[102,103] but this does not establish equivalence. In the context of chronic stable angina, PCI remains an important treatment to relieve symptoms but is associated with a small early risk.

Coronary Artery Bypass Graft Surgery

In comparison with medical therapy, CABG improves long-term (10-year) survival in patients with stable angina. Subgroup analysis demonstrates that patients with greater than 50% left main stem stenosis had the greatest survival benefit with CABG.[12,138,173] Survival benefits are also seen in patients with three-vessel disease or two-vessel disease that includes proximal LAD stenosis.[12,138] However, patients with two-vessel disease without proximal LAD stenosis or one-vessel disease do not derive any survival advantage from CABG. Patients with abnormal left ventricular function or strongly positive exercise tests derive greater absolute survival benefit from CABG than from medical therapy.

The survival benefit for coronary artery surgery is, therefore, related to the severity of coronary artery disease. Those with the most severe coronary artery disease have the most to gain from coronary artery surgery, and the benefits are greatest in those with left main stem disease, followed by those with three-vessel disease and then by those with one- or two-vessel disease (see Figs. 12–10 and 12–13). Further observational evidence from the Duke University data base supports the observation that patients with two-vessel disease that involves the proximal LAD and those with three-vessel disease have a lower hazard ratio (for mortality) with CABG than do those who receive medical treatment.[106]

It is important to note that in the trials cited earlier, a significant number of patients with three-vessel disease who were initially randomized to medical therapy crossed over to surgery (41% at 10 years). These studies are, therefore, not a sole comparison of surgery and medical therapy but rather a comparison of initial surgical versus initial medical treatment. This factor has diluted the observed benefits of CABG because a high proportion of the patients initially randomized to medical therapy may have gained a survival benefit from surgery. In the meta-analysis of Yusuf and colleagues,[138] only 9.9% of patients received an internal mammary artery graft and only 25% of the patients who underwent CABG were receiving antiplatelet agents. These randomized controlled trials may have underestimated the benefits of CABG and do not take into account improvements in surgical techniques (see Fig. 12–10).[174]

POTENTIAL FUTURE THERAPIES

Angiogenesis

Angiogenesis is a novel area of interest that has therapeutic potential in patients considered unsuitable for conventional means of coronary revascularization. Growth factors that can induce new vessel growth—such as vascular endothelial growth factor (VEGF) or basic fibroblast growth factor—are administered into areas of ischemic myocardium, either as the mature peptide[175] or via gene transfer therapy,[176,177] to enhance collateral blood vessel formation and thereby improve myocardial blood flow and perfusion.

Early studies in lower-limb circulation[178] have suggested that there may be major clinical benefits from such an approach in patients with peripheral vascular disease and critical ischemia. Although there are concerns with regard to the potential for sarcomatous transformation, preliminary pilot studies within the coronary vascular bed have suggested that the implantation of microspheres impregnated with basic fibroblast growth factor[175] or gene transfer of VEGF[176,177] into ischemic, viable, but not graftable territories of myocardium can result in a significant enhancement of myocardial perfusion without provoking adverse effects.

Heart Failure

Chapter 13

Risk Factor Management and Lifestyle Modification in Heart Failure

Gene A. Gulliver and Nancy K. Sweitzer

CHAPTER CONTENTS

Heart failure is the final common pathway of most other cardiac diseases, including coronary heart disease (CHD), valvular disease, congenital heart disease, and hypertensive heart disease. Heart failure affects 5 million people in the United States, and millions more are at risk for developing heart failure. The cost to Medicare for beneficiaries with heart failure is 431% that of other beneficiaries; heart failure costs an estimated 28 billion dollars each year in the United States.[1] Despite tremendous advances in treatment during the past 25 years, heart failure remains a largely incurable and eventually fatal disease. It is increasingly argued that prevention of heart failure will have a greater impact to reduce the societal and individual burdens of this disease than any advances in treatment of established heart failure, owing to the size of the population at risk.[2] Risk factor management and lifestyle modification in heart failure will arguably have the greatest impact when focused on patients with early stages of disease.

The 2001 ACC/AHA Guidelines for the Prevention and Treatment of Chronic Heart Failure in the Adult first introduced the concept of preclinical heart failure as stages A and B, reinforced in the 2005 revision.[3,4] The stage A patient has risk factors for heart failure without detectable cardiovascular abnormalities or disease. The stage B patient has asymptomatic left ventricular dysfunction. (Fig. 13–1) To impact the tremendous economic and social costs due to heart failure, it is essential to target aggressive risk factor management and lifestyle modification to these early-stage heart failure patients. Risk factor management and lifestyle modification are also of critical importance to prevent disease progression in later-stage heart failure patients. Because risk assessment for heart failure is not part of routine clinical practice, increasing awareness in the medical community of the importance of identification and treatment of the stage A heart failure patient remains a great challenge. Most patients at risk for heart failure, and many with the disease, are unaware of the disease, and may attribute symptoms of fatigue and exertional intolerance to "normal" aging.

HEART FAILURE RISK ASSESSMENT

Successful heart failure risk assessment and risk reduction involve several objectives. First, appropriate recognition of risk must be achieved. Historically, recognition of heart failure risk in the medical community has been suboptimal. Although routine assessment of risk factors for coronary heart disease has been widely incorporated into medical practice, heart failure is rarely identified or discussed as a risk with patients, particularly in the large number of hypertensive patients at risk. Consequently, the vast majority of patients at risk for heart failure are neither aware of the disease nor of their risk of developing heart failure. In fact, as many as 25% of patients diagnosed with heart failure are unaware of the diagnosis.[5] Although many potential risk factors have been identified for heart failure (Table 13–1), simple, rapid risk assessment schemes similar to the coronary heart disease (CHD) risk estimates based on the Framingham Heart Study have not been developed.[6] Much of heart failure risk is clustered in a few risk factors, particularly CHD, hypertension, and diabetes.

Following identification of risk factors for heart failure, appropriately aggressive treatment must be initiated. Appropriateness is determined to an extent by the age of the patient because risk of new heart failure is significantly increased in the elderly. In addition, clustering of risk factors and magnitude of risk are important to recognize. In patients with multiple risk factors, short-term risk is elevated, and individual risk factors should be treated more aggressively, as is routine in the prevention of CHD.

Finally, optimal risk management in heart failure requires continual reassessment of risk. A patient at low risk for heart

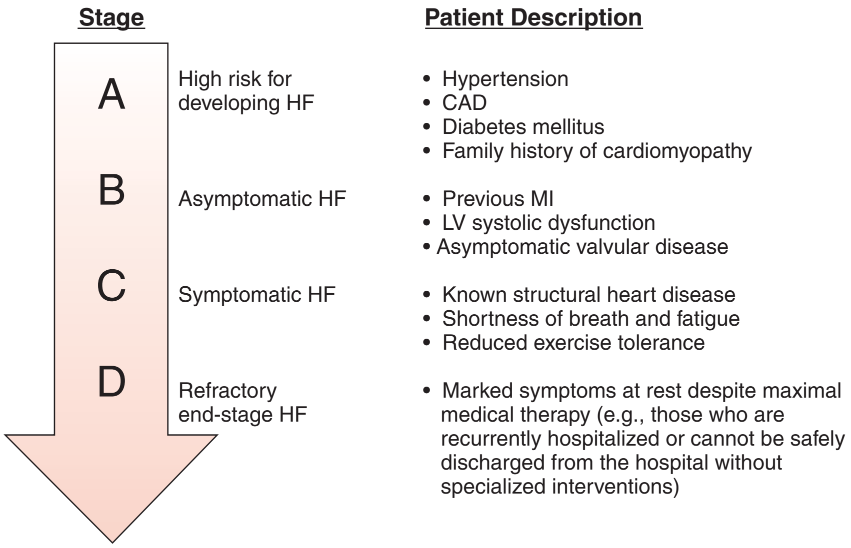

Figure 13–1 The ACC/AHA classification system for heart failure (heart failure).CAD, coronary artery disease; HF, heart failure; LV, left ventricular; MI, myocardial infarction.

Table 13–1 Identified Heart Failure Risk Factors

Coronary heart disease[7,10,13,28,29,34,35,73,170-172]	Male gender
Hypertension[7,10,13,55,60,61,86,173-180]	Alcohol[106,108,112]
Diabetes[65-67,73,74,79,181-183]	Atrial fibrillation[184,185]

failure at age 45 may have significantly increased risk at age 55 after a myocardial infarction. Therefore, at each office visit, a component of the interaction should be dedicated to assessment and treatment of heart failure risk factors.

Risk Factors for Heart Failure

Many studies have explored risk factors for heart failure (see Table 13–1). Fewer studies have demonstrated the impact of treating risk factors on incidence of heart failure. Of the risk factors shown in Table 13–1, coronary heart disease (CHD), hypertension, and diabetes mellitus account for the majority of heart failure cases and carry the highest population-attributable risks (Fig. 13–2). Two large population cohort studies have provided invaluable data about heart failure risk: the Framingham Heart Study[7-12] and National Health and Nutrition Examination Survey 1 (NHANES).[13]

Risk for Heart Failure Secondary to Age, Gender, and Ethnic Background

Although not modifiable, demographic factors must be incorporated into risk assessment for heart failure. In the Framingham cohort, lifetime risk of developing heart failure is 21.0% for men and 20.3% for women aged 40 to 94 years old (Fig. 13–3).[7] Lifetime risk for heart failure does not change as age increases, which is unusual for chronic diseases. The result is a dramatically higher short-term risk for heart failure in elderly patients compared with younger patients. The extremely high short-term risk of heart failure in the elderly is under-recognized. Many diseases exhibit a decrease in lifetime risk during the elderly years as competing diseases of the elderly gain prominence. Heart failure incidence, in fact, is so increased in the elderly years, that competing comorbidities never overcome the risk of heart failure. As a result, aggressive risk factor assessment and management are warranted in the elderly, a traditionally undertreated group.[14,15]

Male gender is consistently associated with increased heart failure risk.[7,16] Heart failure risk is also elevated among African-Americans owing to the high prevalence of predisposing comorbidities, such as hypertension and diabetes.[13] African-Americans develop heart failure at an earlier age and present with more severe and advanced disease than do whites.[17-19] The underlying pathophysiology and response to treatment in African-Americans may also be different from those in white patients.[20,21]

Risk for Heart Failure Secondary to Coronary Heart Disease

It is clear that, in large part, assessing risk for heart failure is indistinguishable from CHD risk assessment. The majority of patients with systolic heart failure in developed countries have ischemic heart disease as the underlying etiology.[13,22] The

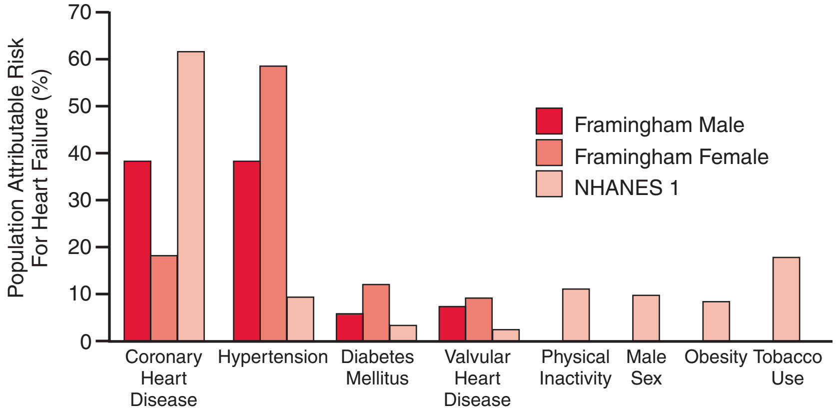

Figure 13–2 Population-attributable risk for heart failure for major heart failure risk factors—as determined by the Framingham Heart Study and the National Health and Nutrition Examination Survey 1 (NHANES).[13]

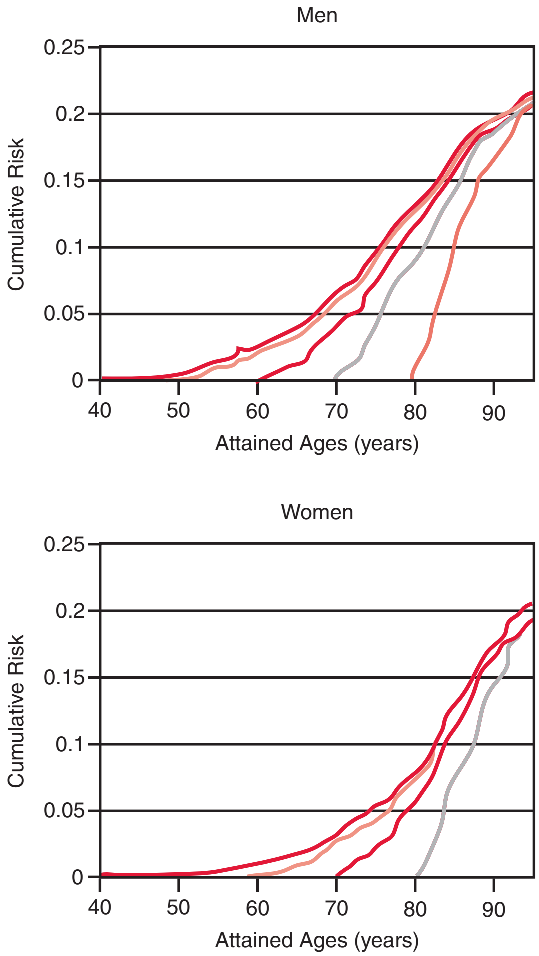

Figure 13–3 Cumulative risk for heart failure at selected index ages for men and women in the Framingham Heart Study. Lifetime risk for heart failure for given index age is cumulative risk through age 94 years. (Redrawn from Lloyd-Jones DM, Larson MG, Leip EP, et al: Lifetime risk for developing congestive heart failure: The Framingham Heart Study. Circulation 2002;106:3068-72.)

Framingham data demonstrate that men and women with angina have a 1.4 and 1.7 increase in relative risk for future heart failure, respectively, whereas after myocardial infarction, relative risk of future heart failure is markedly increased to 6.3 for men and 6.0 for women (see Fig. 13–2).[10] Because of a low prevalence of CHD in the Framingham cohort, the calculated population-attributable risk for heart failure due to ischemic heart disease is comparatively low, 34% for men and only 13% for women. In contrast, in NHANES there is a 62% population-attributable risk for heart failure due to CHD.[13] In the Cardiovascular Health Study, 44% of new heart failure was associated with a new CHD event.[23] It is clear that aggressive primary and secondary prevention of myocardial infarction will reduce the incidence of heart failure.

There are data evaluating the efficacy of treatment to reduce risk for heart failure in stages A and B heart failure patients with ischemic heart disease or disease equivalent. In stage B patients with a prior MI, asymptomatic left ventricular dysfunction, and no symptoms of heart failure, ACE inhibitors (ACEI) and β-blockers have been shown to delay onset of heart failure symptoms and reduce death.[24-27] The Heart Outcomes Prevention Evaluation (HOPE) trial enrolled patients with known vascular, disease or diabetes mellitus combined with multiple risk factors. Subjects were randomized to ramipril 10 mg or placebo.[28] A 20% reduction in future heart failure was noted in the ramipril-treated patients. Likewise, a post-hoc analysis of patients from the Scandinavian Simvastatin Survival Study (4S) trial examined CHD patients treated with simvastatin versus placebo, and found a 21% reduction in future risk of heart failure in patients treated with simvastatin.[29] Interestingly, in both the HOPE and 4S trials, approximately one half of the heart failure risk reduction was due to secondary prevention of myocardial infarction. The other one half of the risk reduction could not be explained by MI prevention, suggesting that these drugs may have effects to prevent heart failure in addition to their effects to prevent MI, perhaps related to neurohormonal, myocardial remodeling, or vascular effects.[30-33] The Treating to New Targets [TNT] trial tested the efficacy of intensive lipid-lowering therapy in 10,001 patients with CHD (stages A and B heart failure) and a mean LDL of <130 mg/dL. Subjects were randomized to atorvastatin 10 mg or 80 mg daily with a median follow-up of 4.9 years. There was a 25% reduction in hospitalization for heart failure in the higher dose atorvastatin group—suggesting that intensive lipid-lowering therapy prevents development of heart failure.[34] In the clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial more than 12,000 patients with acute coronary syndromes were randomized to clopidogrel or placebo.[35] There was a significant 18% reduction in incidence of in-hospital heart failure in the clopidogrel-treated group, suggesting that more

aggressive antiplatelet therapy may have effects to reduce heart failure risk, perhaps through increased myocardial salvage.

In the patient with established stages C and D heart failure due to ischemic heart disease, aggressive secondary prevention is, of course, warranted. β-Blockers and ACE inhibitors should be prescribed to all patients with systolic dysfunction. Some controversy exists about the use of aspirin in patients with heart failure owing to the potential detrimental effects of inhibition of prostaglandin synthesis by aspirin.[36-39] Several trials, however, suggest no impairment in ACE inhibitor efficacy in aspirin-treated patients, and it is routine to treat patients with ischemic heart failure with daily low-dose aspirin therapy.[40-44] Until data are available about the safety of aspirin in heart failure patients without CHD, it has been recommended that aspirin not be used for primary prevention in the patient with nonischemic cardiomyopathy, and the usefulness of aspirin in CHD patients without recent ischemic events has been questioned.[39] There is also some controversy over lipid-lowering therapy. Increasing data suggest that lipid-lowering therapy is of benefit in patients with heart failure, including those with nonischemic disease and diastolic dysfunction.[45-48] Some, however, have argued that aggressive lipid lowering may be harmful in subjects with advanced heart failure, based on the association between low lipid levels and increased mortality in advanced heart failure populations.[49-51] A final controversial area is that of antioxidant vitamin use in heart failure. Despite a reasonable scientific rationale, results in trials of antioxidant vitamins have been disappointing, and patients in the vitamin E (400 IU/day) arm of the HOPE trial showed an increased risk of heart failure and hospitalization for heart failure.[28,52,53]

Although the link between CHD and heart failure is clear, the impact made by aggressive primary and secondary prevention remains largely undefined. Although the data just mentioned begin to explore this issue, future incidence of heart failure has not been regularly monitored in trials of CHD prevention. Nevertheless, it remains inarguable that aggressive preventive therapies in the patient with known CHD are warranted and will likely reduce the future burden of heart failure if applied universally.

Risk for Heart Failure Secondary to Hypertension

Hypertension is an important contributor both to heart failure incidence and heart failure exacerbations. In the Framingham study, the presence of hypertension increased heart failure risk approximately twofold in men and threefold in women (see Fig. 13–2).[10] The prevalence of hypertension is high in the Framingham study, giving a population-attributable risk of 40% for men, and 60% for women. Although ischemic heart disease and hypertension contributed equally to development of heart failure in men in the Framingham study, hypertension was much more predictive of future heart failure development in women. In the NHANES population there is a substantially lower 10% population-attributable risk for heart failure due to hypertension (see Fig. 13–2).[13]

The various components of blood pressure have been studied to determine their contribution to future development of heart failure. Increases in systolic blood pressure and pulse pressure are associated linearly with risk of heart failure, without a threshold.[54,55] Interestingly, there appears to be a U-shaped association between diastolic BP and heart failure with increased risk at both the lowest and highest diastolic pressures.[55] This is likely due to the association between low diastolic blood pressure and increased arterial stiffness, with increased pulsatile load on the left ventricle contributing to heart failure development.

Numerous studies have demonstrated that treatment of hypertension reduces heart failure risk. Meta-analyses of trials of hypertension treatment with heart failure identified as an endpoint demonstrate a 22% to 80% reduction in risk of heart failure (select trials are shown in Table 13–2).[56,57] Agents shown to achieve reductions in incidence of heart failure include diuretics, ACE inhibitors, β-blockers, and probably angiotensin-receptor blockers.[58,59] Other antihypertensive medications, such as α-blockers and calcium channel blockers may increase heart failure risk. In the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), treatment of hypertension with doxazosin increased risk of future development of heart failure compared to chlorthalidone.[60] α-Adrenergic blocking drugs should not be used as an antihypertensive agent in patients at risk for heart failure. Similarly, the International Nifedipine GITS Study: Intervention as a Goal in Hypertensive Treatment (INSIGHT) trial found an increased risk of future heart failure in patients treated with nifedipine compared with those treated with the diuretic co-amilozide.[61] These data suggest that calcium channel blockers should not be used as first line agents in hypertensive patients at risk for heart failure, reinforcing the concept that the choice of antihypertensive medication, especially in patients at risk for heart failure, is of significant importance.

Heart failure is a complex endpoint in hypertension trials. Although diuretics have been associated with decreased inci-

dence of heart failure, it is not known if this might, in fact, be due to lower incidence of edema in diuretic-treated patients, and thus reduced diagnosis of heart failure. Conversely, lower extremity edema is a known side effect of calcium channel blockers; whether this leads to overdiagnosis of heart failure in this subgroup in clinical studies is unknown. The fact that there has been no uniform definition of heart failure in these studies further clouds the data. Nevertheless, it is clear from multiple studies that there is no substitute for effective treatment of hypertension. Until further data are available, the Seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure provides appropriate guidelines.[62]

Risk for Heart Failure Secondary to Diabetes Mellitus

Diabetes has been shown to be strongly associated with increased heart failure risk; however the interaction between diabetes and heart failure is complex, with diabetes being an etiology as well as a consequence of heart failure.[63,64] Poor glycemic control may be related to heart failure via multiple mechanisms—among them promotion of atherosclerosis and subsequent coronary heart disease; development of diabetic cardiomyopathy, possibly related to microangiopathy; and metabolic derangement reducing efficiency of myocardial performance.[65] In the Framingham study, the presence of diabetes mellitus doubles the risk of future heart failure development in men, and quadruples the risk in women.[11] Because of a relatively low prevalence of diabetes in this cohort, the population-attributable risk is 6% and 12% for men and women, respectively (see Fig. 13–2). In NHANES, the population-attributable risk of heart failure due to diabetes mellitus is 3.1%. With the rising incidence of type 2 diabetes mellitus, these population statistics will undoubtedly change, and diabetes will gain increasing prominence as a risk factor for heart failure.

The correlation between glycemic control and heart failure incidence has been explored in a large cohort of type 2 diabetic patients.[65] In this study, each 1% increase in hemoglobin A1C was associated with an 8% increase in risk of heart failure (Fig. 13–4). In a retrospective study evaluating incidence of heart failure in patients with impaired glucose tolerance, the incidence of heart failure increased as the level of fasting blood glucose (FBG) increased from <90 to 125.[66] Additionally, the Uppsala Longitudinal study of Adult Men demonstrated that degree of insulin resistance was associated with heart failure incidence independent of other risk factors.[67] These studies demonstrate a graded increase in heart failure risk from subclinical insulin resistance to impaired fasting glycemic control to diabetes mellitus. It has not been demonstrated that tighter glycemic control reduces heart failure risk in patients with diabetes.

When diabetes is clustered with other risk factors, risk of heart failure development is extremely high, and the need for aggressive treatment of all risk factors is even more compelling. The patient with diabetes appears to be more susceptible to ischemic injury of the myocardium. In studies comparing cardiac function in nondiabetic and diabetic patients after treatment with thrombolytics for acute myocardial infarction, patients with diabetes demonstrated impaired recruitment of contractile reserve in noninfarct segments,[68,69] greater reduction in global LV function,[70] and greater incidence of heart failure.[71,72]

The Type 2 Diabetes, Hypertension, Cardiovascular Events and Ramipril (DIABHYCAR) study defined risk factors for progression to heart failure among diabetic patients.[73] Age, history of CHD, urine protein, HgbA1C, and smoking >15 cigarettes a day independently predicted heart failure development in multivariate analysis (Table 13–3). In the OASIS

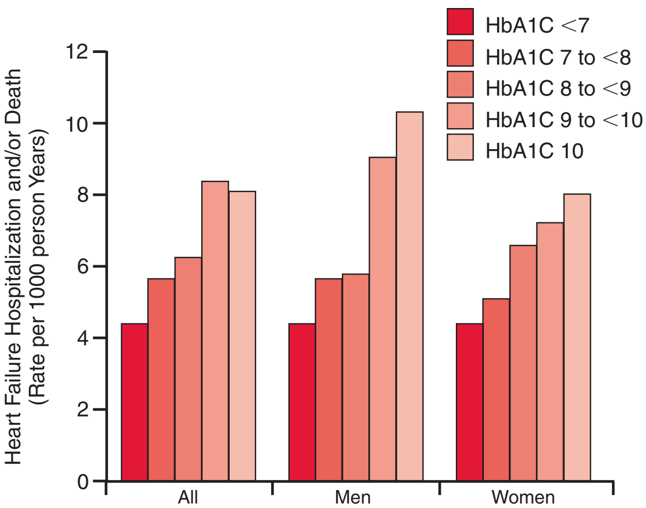

Figure 13–4 Rate of heart failure hospitalization and death in 48,858 persons stratified by hemoglobin A1C level (*P* value for trend = .0001). (Adapted from Iribarren C, Karter AJ, Go AS, et al: Glycemic control and heart failure among adult patients with diabetes. Circulation 2001;103:2668-73.

Table 13–3 Predictors of Heart Failure in Diabetes Mellitus

	Hazard Ratio	95% Confidence Interval	*P* Value
Age (for every 10-year increase)	1.72	1.68-1.76	<0.0001
History of cardiovascular disease	2.55	1.80-3.62	<0.0001
Urine albumin/creatinine ratio (per 10-fold increase)	2.30	1.71-3.09	<0.0001
Hemoglobin A1C (for every 1% increase)	1.80	1.08-1.29	0.0003
Smoking >15 cigarettes/day	1.98	1.15-3.40	0.013

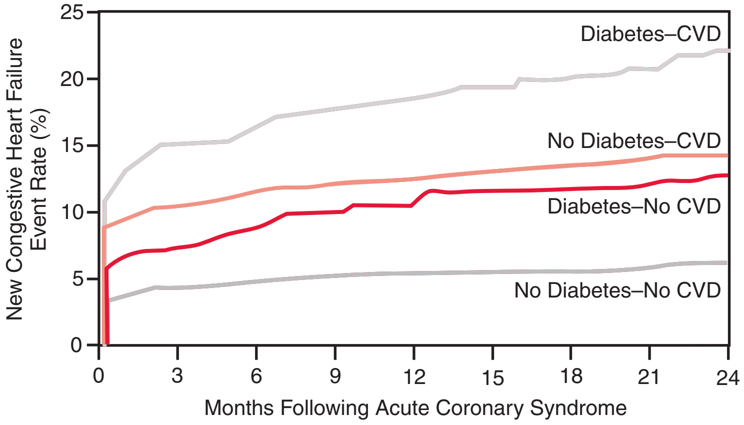

Figure 13–5 Risk of future heart failure in patients presenting with acute coronary syndromes, stratified by the presence or absence of known diabetes or cardiovascular disease (CVD) at the time of presentation. Data from the Organization to Assess Strategies for Ischemic Syndromes (OASIS) registry. (Redrawn from RW Nesto, Rev Cardiovasc Med 2004;5:1-8; adapted from Malmberg K, Yusuf S, Gerstein HC, et al: Impact of diabetes on long-term prognosis in patients with unstable angina and non–Q-wave myocardial infarction: Results of the OASIS [organization to assess strategies for ischemic syndromes] registry. Circulation 2000;102:1014-9.)

registry, patients were enrolled at the time of an acute myocardial infarction and future risk of heart failure was evaluated.[74] Those patients without a previous history of diabetes mellitus or known cardiovascular disease at the time of their acute presentation demonstrated an approximate 5% risk of heart failure over the next 2 years. If at presentation there was a history of diabetes mellitus, but no history of cardiovascular disease, or the inverse, then the risk of heart failure over the next 2 years approximately doubled. However, in patients with both a history of diabetes mellitus and known cardiovascular disease, an approximate 20% risk of new heart failure over the next 2 years was observed (Fig. 13–5).

Heart failure risk also has been examined in patients with combined hypertension and diabetes. The United Kingdom Prospective Diabetes Study Group (UKPDS) documented the importance of blood pressure control in those patients with diabetes mellitus to reduce heart failure.[75] In this study, 1200 subjects with type 2 diabetes were randomized to "tight" blood pressure control (treating to less than 150/85) or less strict blood pressure control (treating to less than 180/105). Over 8 years of follow-up, the authors reported a 50% reduction in development of heart failure in the tight blood pressure control group.

The Losartan Intervention for Endpoint Reduction (LIFE) trial provides yet more detail with regard to the importance of specific therapies for treatment of hypertension in the setting of diabetes mellitus.[58] Of 9193 patients randomized to treatment with losartan 50 mg or atenolol 50 mg, a subgroup of 1195 subjects had both hypertension and diabetes. Although overall the incidence of heart failure was not different between individuals receiving the two therapies at 5 years of follow-up, the diabetic subjects had significantly fewer hospitalizations for heart failure when treated with losartan (5% versus 9%; $P = 0.019$), emphasizing the importance of angiotensin system blockade as a therapeutic maneuver in subjects with diabetes mellitus. The Glycemic Effects in Diabetes Mellitus: Carvedilol-Metoprolol Comparison in Hypertensives (GEMINI) trial investigated effects of the two β-blockers on glycemic and metabolic control in patients with diabetes and hypertension.[76] Carvedilol was associated with improvement in components of the metabolic syndrome and no disturbance in glycemic control. Incidence of clinically important endpoints, such as heart failure, was not reported in this short-duration study.

Investigators have attempted to determine possible pathophysiologic mechanisms for the detrimental synergy between diabetes and hypertension.[77] Interestingly, although diabetic hearts demonstrate hypertrophy, cavity dilation, and depressed ventricular performance, these alterations are more severe in patients with combined diabetes and hypertension. In addition, the risk of heart failure in diabetics has been reported to be out of proportion to the degree of ventricular remodeling seen,[78] suggesting that diastolic abnormalities are important in the diabetic population. Studies have also demonstrated apoptosis and necrosis in ventricular myocardial biopsies obtained from both diabetic-hypertensive patients and diabetic patients, with similar levels of apoptosis in both the diabetic and diabetic-hypertensive patients, but increased levels of cellular necrosis in patients with both diabetes and hypertension.[77] An associated increase in angiotensin II labeling in myocytes and endothelial cells was more significant in patients with diabetes and hypertension, than in patients with diabetes alone.

The aforementioned findings provide a possible pathophysiologic basis for the importance of blockade of the renin-angiotensin-aldosterone system in patients with both diabetes and hypertension. The importance of blockade of this system has also been demonstrated when diabetes is combined with renal disease. In the Reduction of Endpoints in NIDDM with Angiotensin II Antagonist Losartan (RENAAL) trial, diabetic patients with overt nephropathy were randomized to either losartan (50 to 100 mg once a day) or placebo.[79] The incidence of first hospitalization for heart failure was reduced by 30% in the group treated with losartan—further emphasizing the importance of RAAS blockade.

Risk for Heart Failure Secondary to Metabolic Syndrome

The relation between metabolic syndrome and heart failure is also being explored. The Adult Treatment Program III of the National Cholesterol Education Program has defined the metabolic syndrome as the presence of three or more of the following: (1) hypertension; (2) impaired fasting glucose; (3) low HDL cholesterol; (4) increased triglycerides; (5) and abdominal obesity. In one case control study, patients with metabolic syndrome and an acute myocardial infarction had an increased incidence of severe in-hospital heart failure.[80] Of the five metabolic syndrome components, hyperglycemia was the major determinant of severe heart failure. In the Women's Ischemia Syndrome Evaluation study, 25% of women referred for coronary angiography met criteria for the metabolic

syndrome. In subjects with angiographically significant CHD, the metabolic syndrome was associated with higher rates of major adverse cardiovascular events including stroke and heart failure.[81]

Risk for Heart Failure Secondary to Renal Disease

Renal disease, especially microalbuminuria, is strongly associated with increased incidence of first hospitalization for heart failure.[82] The mechanism by which renal disease causes heart failure is unknown, although vascular stiffening, uremic toxins, and impaired fluid balance have been implicated.[83-85] Microalbuminuria may be a marker of poor glycemic control, hypertension, inflammation, and/or endothelial dysfunction. In the DIABHYCAR study, a 10-fold increase in urinary albumin concentration more than doubled the risk of heart failure.[73] It is unknown whether treatment of renal disease, including microalbuminuria, will independently reduce the risk of future heart failure. The risk for heart failure secondary to renal dysfunction was evaluated by analyzing data obtained from the Heart Outcomes Prevention Evaluation (HOPE) trial.[82] Patients were stratified by the presence or absence of microalbuminuria. The risk of heart failure was higher in the group of patients with microalbuminuria, indicating that the presence of renal disease is a marker of risk for heart failure. However, treatment with ramipril did not reduce risk of future heart failure in the microalbuminuric subjects, suggesting that ACE inhibitor therapy was not particularly effective at heart failure prevention in this group of patients with renal dysfunction and microalbuminuria.

Risk for Heart Failure Secondary to Tobacco Use

Smoking cessation is an important component of primary and secondary prevention of both coronary artery disease and heart failure. In one study, after adjusting for hypertension, body weight, and other heart failure risk factors, patients actively smoking at the age of 50 demonstrated a 60% higher risk of future heart failure.[86] Likewise, after adjustment for other risk factors, active smokers in NHANES demonstrated a 45% (men) and 88% (women) increase in the risk of heart failure.[13] In fact, in NHANES, 17% of the population-attributable risk for heart failure was due to cigarette smoking. Independent of tobacco use promoting physiologic abnormalities that increase the risk of coronary artery disease, it has been hypothesized that cigarette smoking induces oxidative stress, which may promote LV remodeling[87] and have direct toxic effects on the myocardium.[88,89] All patients, whether healthy, at risk for heart failure, or with known cardiovascular disease and heart failure, should be counseled to quit smoking as recommended in the ACC/AHA guideline.[4] In addition, cardiologists should be comfortable in prescribing effective treatment to assist with smoking cessation, rather than relying on primary care physicians for this critical intervention.

Risk for Heart Failure Secondary to Valvular Abnormalities

An increased risk for heart failure has been noted in patients with valvular abnormalities, determined both by clinically significant precordial murmurs,[6,9] or diagnostic codes recorded in the medical record.[13,90] Valvular heart disease results in either pressure or volume overload of the ventricle. The left ventricle initially tolerates the overload via compensatory mechanisms such as hypertrophy or dilatation. Over time, however, as in other cardiovascular disorders, chronic hemodynamic overload results in left ventricular dysfunction and eventually overt heart failure.[91] Significant improvement in left ventricular function and survival has been achieved with surgical management of stenotic and regurgitant diseases of the aortic and mitral valves.[91,92] Survival can be improved with acceptable operative mortality even in the elderly, and there is no reason to delay valve surgery in appropriate patients once heart failure symptoms are present.[93,94]

Risk for Heart Failure Secondary to Obesity

The relation between obesity and heart failure risk is complex because obesity invariably clusters with other risk factors. Nevertheless, a number of studies indicate that obesity is a potent predictor of subsequent development of heart failure. Data collected on 5881 participants from the Framingham Heart Study during a mean follow-up of 14 years showed a significant increase in risk of heart failure with increased body mass index (BMI) (Fig. 13–6).[12] In this analysis, heart failure developed in 496 subjects—258 women and 238 men. After adjusting for numerous risk factors, the investigators noted that for each 1 unit increase in body mass index, there was an increased risk of heart failure of 5% for men, and 7% for women. Compared with subjects with normal body mass index, the hazard ratios for development of heart failure in obese men and women were 2.12 (95 % CI: 1.51 to 2.97) and 1.90 (95%CI: 1.30 to 2.79), respectively. These data suggest that incidence of heart failure rises steeply as body weight increases.

Although it has not been definitively demonstrated that weight loss reduces heart failure risk, several studies suggest that weight loss may be an important intervention for regression of left ventricular hypertrophy and prevention of heart failure in obesity. Case reports of extreme weight loss induced by biliopancreatic diversion have reported recovery from severe heart failure with associated near normalization of cardiac structure and function.[95-97] Alpert and colleagues performed echocardiograms on obese patients before and following bariatric surgery and found that weight loss was associated with reductions in left ventricular chamber size, wall stress and mass, and an improvement in diastolic function.[97] In an observational study of patients undergoing gastroplasty compared with controls treated with diet alone, weight loss following surgery correlated with LVH regression independent of reduction in blood pressure.[98] Conventional weight reduction through intensive diet and exercise has also been shown to reduce left ventricular mass.[99] Although LVH regression is associated with improved outcomes in hypertensive patients,[100] there are no data demonstrating reduced cardiovascular events with sustained weight loss in obese patients with LVH.

There are additional data demonstrating that the relation between obesity and heart failure is more complicated. It has been demonstrated repeatedly that obese patients with

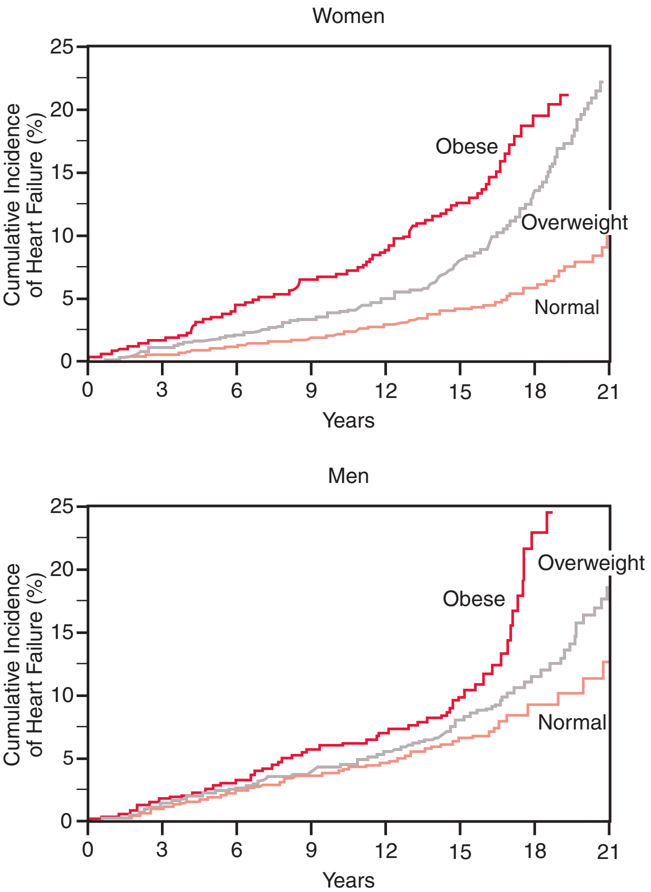

Figure 13–6 Cumulative incidence of heart failure from the Framingham Heart Study, stratified by body-mass index at the baseline examination. The body-mass index was 18.5 to 24.9 in normal subjects, 25.0 to 29.9 in overweight subjects, and 30.0 or more in obese subjects. (Redrawn from Kenchaiah S, Evans JC, Levy D, et al: Obesity and the risk of heart failure. N Engl J Med 2002;347:305-13.)

diagnosed heart failure have a more favorable prognosis than heart failure patients with low, or even normal BMI—the "obesity paradox."[101,102] The term "reverse epidemiology" has been used to describe the phenomenon wherein conventional cardiovascular risk factors, in addition to obesity, are associated with better prognosis in chronic heart failure.[50] Possible explanations of the "obesity paradox" include (1) increased risk in patients with low body weight as a result of a high catabolic state due to the presence of more severe disease with higher levels of proinflammatory cytokines[103]; (2) relatively less neurohormonal activation or greater metabolic reserve in obese patients[104]; and (3) lead-time bias—in that obesity leads to development of symptoms and subsequent diagnosis when at a less advanced stage of disease.[105]

Risk of Heart Failure Secondary to Alcohol Consumption

The relation between excessive alcohol consumption and cardiomyopathy, the result of toxic injury to the cells of the myocardium, is well accepted.[106,107] In a Swedish cohort of men, history of alcohol abuse was associated with an increased risk of heart failure.[108] A history of heavy alcohol use has been shown to be correlated with systolic dysfunction,[109-111] whereas mild-to-moderate alcohol consumption has been inversely associated with risk of heart failure[112,113] and after a myocardial infarction, there is a reduced risk of new heart failure in light-to-moderate drinkers (one to ten drinks per week).[114] This effect of mild-to-moderate alcohol consumption to reduce heart failure is possibly mediated by decreasing the risk of CHD and subsequent MI. Patients at risk for heart failure should be counseled to engage in no more than moderate drinking, although abstinence may be appropriate in patients with a history of alcohol abuse.

Risk for Heart Failure Secondary to Sleep-Disordered Breathing

Sleep-disordered breathing (SDB) includes the variants obstructive sleep apnea (OSA) and central sleep apnea (CSA). Among patients with heart failure, sleep-disordered breathing is common, with increased incidence of both OSA and CSA. Approximately one third of patients with heart failure and SDB have CSA.[115] Patients with CSA and heart failure have an increased mortality independent of other known risk factors.[116]

The pathophysiologic link between heart failure and SDB has been explored in a canine model.[117] Inspiration against an occluded airway can lead to an increase in left ventricular afterload, a decrease in preload, and a reduction in stroke volume. The reduced stroke volume may then lead to neurohormonal activation implicated in the primary pathophysiology of heart failure. Additionally, OSA may cause intermittent hypoxia and increased sympathetic tone, provoking myocardial ischemia and further increases in afterload. In a study of over 6400 individuals, the presence of an apnea-hypopnea index >11 per hour was associated with greater than 2.4-fold odds of self-reported heart failure.[118] Whether the sleep apnea contributed to heart failure development is unknown, and although there is a plausible pathophysiologic link, it remains unknown whether SDB can actually cause heart failure.

It has been shown that treatment of diagnosed SDB can result in some improvements in cardiac function. Treatment of CSA with CPAP in heart failure patients in one study improved left ventricular ejection fraction, and, possibly, mortality.[119] In another study, patients with dilated cardiomyopathy and OSA were treated with CPAP and had objective improvements in left ventricular end systolic volume and ejection fraction.[120] The Canadian Continuous Positive Airway Pressure for Patients with Central Sleep Apnea and Heart Failure (CANPAP) trial enrolled 258 patients and demonstrated that patients treated with CPAP had a small improvement in ejection fraction without any effect on mortality.[121]

Risk for Heart Failure Secondary to Depression

The relation between the mind and physical diseases of the body has gained increasing attention. Recent studies have examined depression as a risk factor for heart failure. In the SHEP trial, enrolled subjects were elderly hypertensives who completed a questionnaire at the start of the trial assessing

depression. Over the next 5 years, patients with high depression scores had a higher risk of new heart failure.[122] A similar increase in risk has been found in depressed elderly women without other risk factors for heart failure although no increased risk was seen in men with depression.[123] Among patients with established heart failure, a coincident diagnosis of depression is associated with a worse prognosis.[124,125] These data raise the interesting possibility that treating depression might reduce an individual's risk for heart failure or reduce heart failure morbidity, but this has not been tested.

LIFESTYLE MODIFICATION IN THE HEART FAILURE PATIENT

The majority of Americans are sedentary.[126] Simultaneously, the availability of inexpensive high calorie and processed foods has led to an increase in fat, salt, and caloric intake—correlated with decreased leisure activity.[127] Tobacco use, while declining among adults, has been increasing in adolescents in recent years.[128] Thus, all persons must be aware of the health effects of lifestyle choices, and encouraged to change unhealthful behaviors. There are a number of lifestyle issues of specific importance to the patient with, or at risk for, heart failure.

Heart Failure and Diet

Dietary choices affect heart failure risk in many important ways,[129] including the risk of heart disease associated with a diet high in refined grain products and deficient in fish or fruit and vegetables, the contribution of salt to hypertension in a subset of individuals, and the general contribution of excess calorie intake to obesity, diabetes, and hypertension. It has been demonstrated that diet can influence risk of CHD,[130-132] which would then impact subsequent heart failure risk. Likewise, diet and weight reduction are clearly associated with both reductions in blood pressure[133] and improved glycemic control,[134] both of which would be expected to reduce heart failure risk.

Dietary interventions specifically applied to patients with heart failure include restriction of both sodium intake and fluid intake. Although there are no data to suggest that these dietary interventions reduce heart failure mortality, there is increasing evidence that sodium and fluid restriction improve quality of life. Heart failure patients randomized to sodium and fluid restriction have less edema and fatigue than those eating their usual diet.[135] The patients with sodium and fluid restrictions also had an improvement in physical activity and functional class, whereas levels of physical activity worsened in patients following their usual diet. Noncompliance with diet recommendations among heart failure patients is associated with readmission and longer lengths of stay.[136] There is no evidence that routine use of nutritional supplements can prevent cardiac dysfunction or injury,[137] nor have nutritional supplements or neutraceuticals been shown to have benefit to improve symptoms or outcomes in established heart failure. Excellent patient-oriented educational materials are available in print and on the Web, to assist patients with understanding of dietary recommendations and to provide aids for compliance (see e.g., *www.abouthf.org*).

Heart Failure and Alcohol Consumption

As noted earlier, the precise relation between alcohol consumption and heart failure is unknown. Acute and long-term effects of alcohol in patients with heart failure have recently been reviewed.[138,139] The authors concluded that at least some emerging evidence suggests that light drinking (1 to 14 drinks per week) is safe and even beneficial in heart failure patients with ischemic left ventricular dysfunction, but without benefit in patients with nonischemic left ventricular dysfunction. Men may derive more of the protective benefit of moderate alcohol consumption than women.[13,112] Given the known detrimental effects of alcohol on myocardial function, alcohol should be avoided during periods of clinical instability. Because cardiomyopathy due to alcohol ingestion can recover with abstinence or reduction in alcohol intake to moderate levels,[140] a period of abstinence is advisable in most patients presenting with new heart failure and systolic dysfunction, as alcohol use is often under-reported. Once cardiac function has stabilized, it may be reasonable to permit occasional alcohol use. However, because of the known toxic effects of alcohol on the myocardium, recommendations about alcohol should be made cautiously and tailored to the individual patient.

Heart Failure and Exercise

Skeletal muscle structure and function are abnormal in individuals with heart failure, which contributes to deconditioning and exercise intolerance.[141,142] Heart failure patients also exhibit attenuated peripheral vascular responses to exercise and reduced respiratory muscle endurance.[143,144] Regular exercise improves symptoms, clinical status, and exercise duration in patients with heart failure,[145] perhaps as a result of reversing peripheral abnormalities.[146] In one study, patients with stable heart failure were randomly assigned to exercise training or no exercise for 1 year. Exercise training improved functional capacity, quality of life, and reduced hospital admissions for heart failure.[147] In addition, there was a statistically significant reduction in mortality in the exercise-training group. Exercise also appears to have beneficial effects on ventricular structure and remodeling.[148]

The current NIH-sponsored trial Heart Failure and A Controlled Trial Investigating Outcomes of Exercise Training (HF-ACTION) is designed to investigate the potential benefits of exercise on morbidity and mortality in heart failure patients in great detail. Until those results are available, exercise training should be recommended for all stable outpatients with chronic heart failure able to participate. A typical training regimen begins with very low-level, low-impact exercise such as walking 5 to 10 minutes per day, and increases gradually to 30 or more minutes at a moderate perceived level of exertion at least 5 days a week. Many outpatient cardiac rehabilitation programs have moved beyond caring exclusively for patients with coronary disease and have become experienced and comfortable providing exercise prescriptions and lifestyle advice to heart failure patients.

Heart Failure and Sexual Activity

The maintenance of sexual function has been shown to be a concern among patients with cardiac illness.[149,150] Satisfaction

with sexual relations in patients with heart disease can be affected by medications, exercise capacity, changes in mood and self-esteem, and fear of death by the patient and/or partner. The issue of sexual function has been studied in patients with advanced heart failure.[149] One half of patients reported significant reductions in their sexual satisfaction after the development of heart failure. There were correlations between both 6-minute walk performance and NYHA class, and level of sexual function. There was no significant relation between sexual function and ejection fraction. Sexual activity carries different risks depending on the severity of heart failure.[63] Although NYHA class I patients have minimal risk with sexual activity, risk increases as NYHA class increases. Unstable patients should be advised to abstain from sexual activity until the disease state has stabilized.

Treatment of sexual dysfunction in male subjects with sildenafil citrate has become commonplace. Sildenafil citrate can be used safely in men with erectile dysfunction and mild-to-moderate chronic heart failure, with flexible dosing of sildenafil well tolerated, improving erectile dysfunction, and increasing satisfaction with sexual performance compared with placebo.[151] Indeed, sildenafil may have a role in treatment of advanced heart failure with secondary pulmonary hypertension.[152,153] Patients receiving oral nitrate therapy should

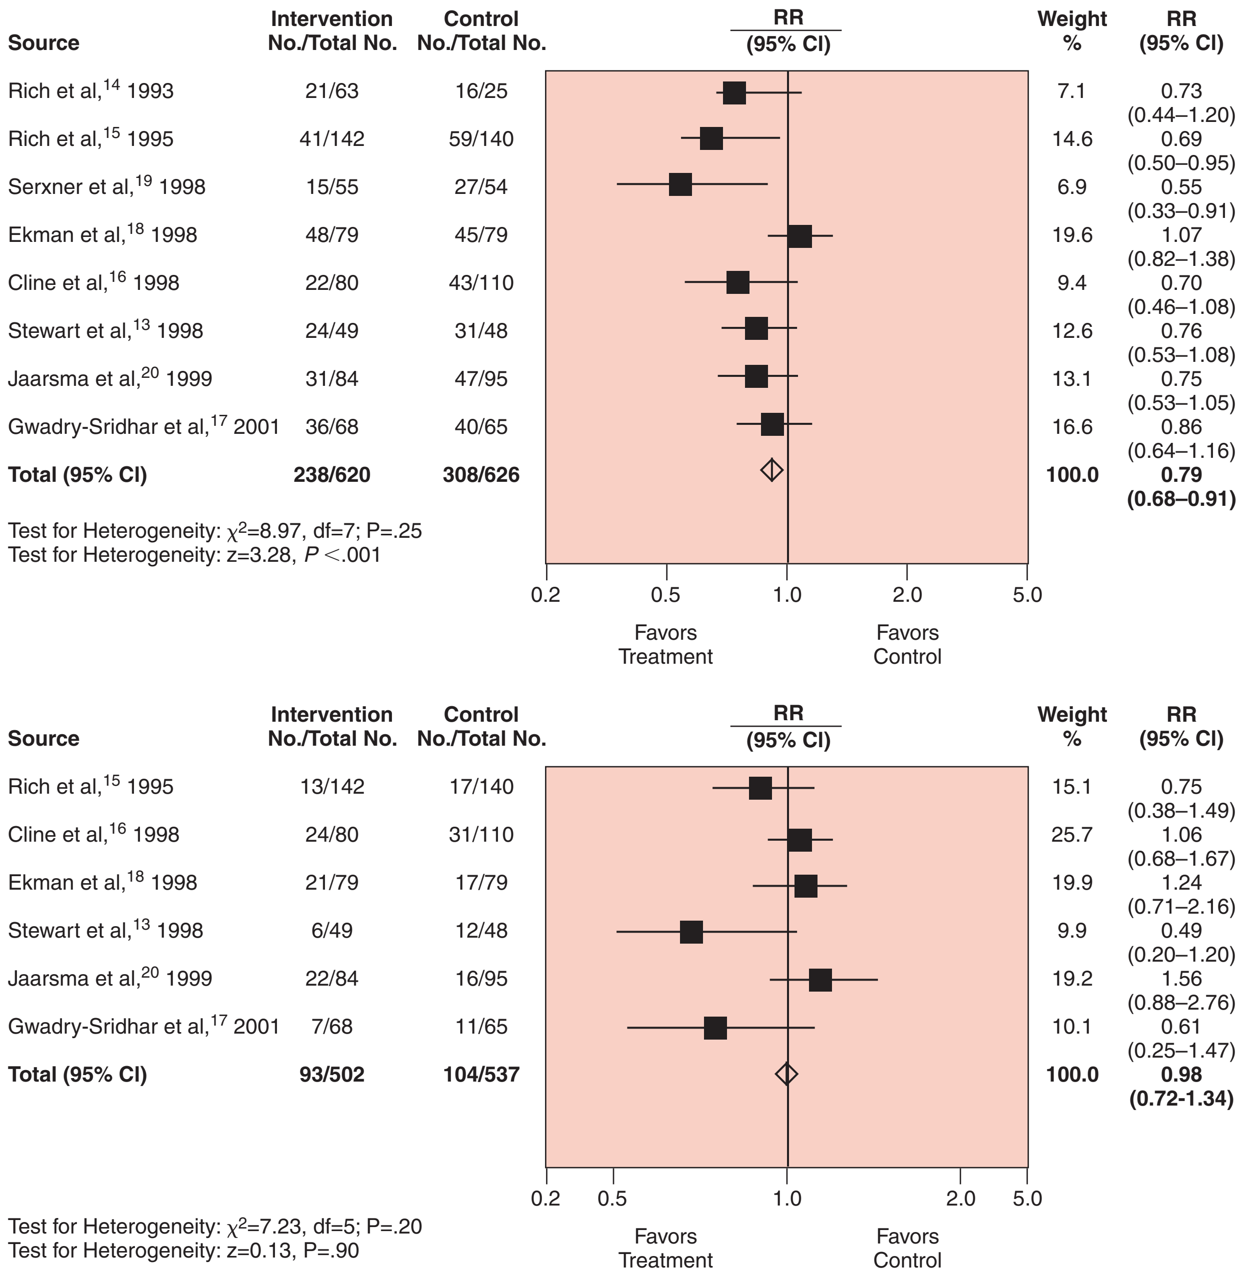

Figure 13–7 Data from a 2004 meta-analysis of heart failure disease management demonstrating a significant reduction in relative risk of heart failure readmission in the pooled analysis, with no effect on relative risk of mortality. RR, relative risk; CI, confidence interval. (Redrawn Gwadry-Sridhar FH, Flintoft V, Lee DS, et al: A systematic review and meta-analysis of studies comparing readmission rates and mortality rates in patients with heart failure. Arch Intern Med 2004;164:2315-20.)

not be prescribed sildenafil because of the risk of significant hypotension.

Heart Failure and Stress

There are no data demonstrating a causal link between mental stress and heart failure. However, as increased circulating catecholamines are implicated in the pathogenesis of heart failure, mental stress may contribute to disease progression through an increase in adrenergic stimulation.[154,155] There is increasing interest in exploring the mind-body relation and its impact in heart failure. The potential link between depression and heart failure is discussed earlier. Meditative and relaxation techniques have been shown to have benefits in patients with heart failure.[156-159] Acupuncture has been shown to decrease sympathetic activation in heart failure patients during periods of mental stress.[160] A randomized controlled trial of mind-body therapy showed improved exercise capacity and quality of life in patients participating in an unblinded Tai Chi program; it is unclear if it was the exercise component, the relaxation component, or the combination that conferred benefit.[161] In select patients, therapies directed at relaxation and stress reduction may hold promise for improvements of quality of life and functional capacity.

Managing Lifestyle Changes: The Role of Comprehensive Heart Failure Management Programs

Disease management has been shown to improve outcomes in heart failure and includes a significant educational component and assistance with lifestyle and risk-factor modification. Disease management programs use a comprehensive approach in patients with heart failure, identifying barriers to optimal disease and symptom control and using team resources to assist patients in their search for improved longevity and well-being.

Initial nonrandomized trials investigated the impact of optimization of drug therapy, intensive patient education, and vigilant follow-up, with particular attention paid to early recognition of decompensation, and identification and aggressive management of significant comorbidities and risk factors. This comprehensive approach resulted in significantly fewer rehospitalizations, lower health care costs, and improved functional and symptom status when compared with rates before referral to the disease management program, or to heart failure patients being treated with conventional care.[162-164] The first randomized clinical trial was a single-center study of high-risk heart failure patients. The authors evaluated the impact of a comprehensive approach that used nurse-directed, multidisciplinary disease management interventions on nonadherence to diet or medications, inappropriate prescribing of medications, and failure to recognize heart failure exacerbations. The results demonstrated a reduction in heart failure readmissions by 56% in 90 days, all readmissions by 29%, and overall cost of care by $460 per patient.[165] Subsequent randomized-controlled trials have demonstrated improvements in mortality, heart failure hospitalizations, all-cause hospitalizations, and reduction or no change in health care costs.[166-168] A meta-analysis has demonstrated a uniform trend for disease management to reduce readmission, with variable effects on mortality (Fig. 13–7).[169] It has been suggested that attention to risk factor and lifestyle management is greater in disease management clinics than with conventional care—possibly because of the high degree of nurse involvement.

Conclusions

A large population is at risk for future development of heart failure. Substantial impact, both economically and socially, will result from maximizing risk reducing therapies in this population. Much of this risk reduction involves lifestyle changes recommended universally to optimize heart health, whereas others are tailored to the individual patient and the risk factors present. Risk for heart failure must be continually reassessed as patients age, and no office visit should pass without a discussion of lifestyle and encouragement to change unhealthful behaviors. Likewise, lifestyle modification can have substantial impact in the patient with established heart failure, particularly to reduce symptom burden and enhance quality of life. Although change is slow, health care providers do influence patients' lifestyle choices and must continually stress the importance of changing often entrenched unhealthful behavior patterns to optimize care of patients with heart failure.

Chapter 14

Pharmacologic Management of Heart Failure in the Ambulatory Setting

Michael M. Givertz and Jay N. Cohn

CHAPTER CONTENTS

Heart failure is a growing public health problem.[1] Over the past decade, there has been considerable advancement in our understanding of the basic pathophysiologic mechanisms that underlie the clinical syndrome of heart failure, the progressive nature of left ventricular remodeling, and associated high mortality rates.[2] Randomized, controlled trials have demonstrated that medications such as angiotensin-converting enzyme (ACE) inhibitors, β-blockers, and aldosterone antagonists reduce the rate of mortality and improve functional status. Nonetheless, the morbidity rate associated with heart failure remains high, and many patients are not optimally treated.[3] These observations stimulated the formulation of specific guidelines for the management of patients with chronic heart failure.[4] A major emphasis in the coming years will include a continued search for more effective therapies as well as a significant educational effort to assist health care providers in the increased use of existing therapies.

This chapter reviews current pharmacologic treatment strategies for ambulatory patients with chronic heart failure. In each section, the most pertinent information regarding pathophysiologic mechanisms is presented, as well as data from important clinical trials that provide the scientific rationale for the treatment recommendations. For areas in which there is strong agreement on medical management, evidence-based recommendations from the ACC/AHA revised guidelines are provided.[4] For areas in which there are few data on mechanisms and treatment, the consensus opinion among heart failure specialists and empiric recommendations are discussed. In addition, each section includes practical recommendations that can be used in everyday clinical practice. A more detailed discussion of the drugs used in the treatment of heart failure can be found in Chapter 23 in HD7ed. Recommendations regarding preventive strategies and risk factor and lifestyle modification are provided in Chapter 13.

PATHOPHYSIOLOGY AND STAGING SYSTEM: TARGETS OF THERAPY

The basic pathophysiology of heart failure, including short-term adaptive mechanisms, chronic myocardial remodeling and neurohormonal, paracrine, and autocrine adjustments is extensively discussed in Chapter 21 in HD7e, as well as in other reviews.[5-7] Three important pathophysiologic concepts have had a substantial impact on the overall treatment strategy. The first concept recognizes the systemic nature of the clinical syndrome of heart failure. Although the primary problem is related to an abnormality in the myocardium, many of the manifesting signs and symptoms are related to dysfunction of end organs—including the lungs, liver, and kidneys—as well as skeletal muscle. The fact that heart failure is a systemic process makes it unlikely that any single therapy will offer a complete treatment response. A second important concept involves the interaction between myocardial dysfunction, activation of neurohormonal systems, and disease progression (Fig. 14–1). This model emphasizes the fact that although heart failure is related to a primary abnormality in myocardial function (genetic or acquired), further impairments in myocardial function, as well as progressive hypertrophy, dilatation or both, can occur in the absence of additional direct injury to the heart. This model can also help to explain the absence of signs and symptoms of heart failure in some patients who have significant ventricular dysfunction, and provides the rationale for therapy with ACE inhibitors and β-blockers in patients with asymptomatic left ventricular dysfunction. Finally, this model emphasizes the observation that treatments that do not have an intrinsic action on the primary myocardial abnormality can still have substantial benefits in heart failure. Thus, ACE inhibitors reduce vasoconstrictor tone and angiotensin-mediated toxicity in the heart, vasculature, and kidneys, and are associated with marked

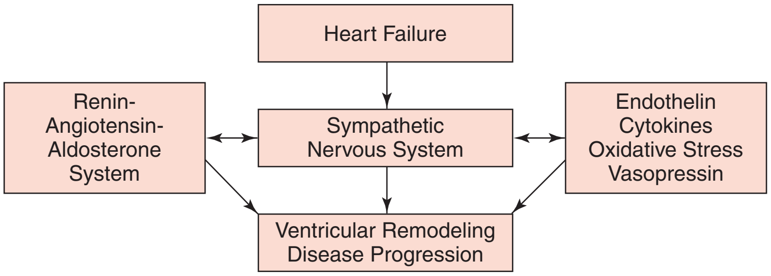

Figure 14–1 Proposed sequence of events in the progression of heart failure. After an initial injury, various secondary mediators such as norepinephrine, angiotensin, and mechanical stress act on the myocardium to cause ventricular remodeling. Additional biological mediators, including endothelin, proinflammatory cytokines, and reactive oxygen species, are upregulated in heart failure and contribute to disease progression.

Table 14–1 Drugs in Heart Failure: Divergent Effects on Therapeutic Goals

Drug	Mortality	Exercise Tolerance	Quality of Life
ACE inhibitor	↓ 20%	Mild improvement	Mild improvement
β-Blocker	↓ 35%	No or mild improvement	No or mild improvement
Aldosterone antagonist	↓ 30%	No or mild improvement	Mild improvement
Digoxin	No effect	Mild improvement	Unknown
Diuretic	Unknown	Moderate improvement	Moderate improvement

ACE, angiotensin-converting enzyme.

Table 14–2 Stage-Based Pharmacologic Therapy of Heart Failure

Stage	Drug	Selected Indications
A	ACE inhibitor or ARB	Vascular disease, diabetes, hypertension
B	ACE inhibitor or ARB	Recent or remote MI, asymptomatic LVD, hypertensive LVH
	β-Blocker	Recent or remote MI, asymptomatic LVD
C	ACE inhibitor or ARB	All patients unless contraindicated
	β-Blocker	All patients unless contraindicated
	Diuretics	Fluid retention
	Aldosterone antagonist	Severe heart failure, post-MI heart failure, or LVD
	Hydralazine and nitrates	Symptomatic heart failure, African Americans
	ARB (on top of ACE inhibitor)	Symptomatic heart failure
	Digoxin	Symptomatic heart failure, AF
D	ACE inhibitor or ARB	All patients unless contraindicated or not tolerated
	β-Blocker	Stable NYHA class IV
	Diuretics	Fluid retention
	Digoxin	AF with rapid ventricular response
	Positive inotropes	Bridge to transplant or end of life

ACE, angiotensin-converting enzyme; AF, atrial fibrillation; ARB, angiotensin receptor blocker; MI, myocardial infarction; LVD, left ventricular dysfunction; LVH, left ventricular hypertrophy; NYHA, New York Heart Association.

improvement in symptoms and in the survival rate. In contrast, drugs that have been shown to activate neurohormonal pathways (e.g., oral positive inotropes) have a neutral or adverse effect on long-term survival.

A third concept that has evolved from randomized clinical trials is that all therapeutic interventions must be critically examined with respect to two different but equally important endpoints: an improvement in symptoms or quality of life and an improvement in survival. Although it is preferable that all interventions have a concordant effect on these endpoints, this is not always the case (Table 14–1). For example, diuretics are very effective in reducing signs and symptoms of heart failure, but their effects on survival are unknown. In contrast, β-blockers reduce hospitalizations and prolong survival, but their effects on exercise tolerance and quality of life are less evident. The distinction between the two endpoints is also reflected in prioritization of treatment for different patient subgroups. For example, patients with asymptomatic left ventricular dysfunction do not require therapy that will reduce symptoms, but they benefit from treatment that slows disease progression and prolongs life. In contrast, a patient with advanced heart failure is benefited by any treatment that relieves symptoms at the end of life.

In 2001, the writing committee of the ACC/AHA guidelines proposed a new approach to the classification of heart failure that emphasized both the development and progression of the disease.[4] Stage A and B patients are at high risk for developing heart failure. Stage A patients are those without

structural heart disease, and stage B patients are those with structural heart disease, but without signs or symptoms of heart failure. Stage C and D patients have structural heart disease with earlier or current symptoms of heart failure (stage C) or refractory heart failure requiring specialized interventions (stage D) (see Fig. 13–1 for examples). This staging system recognizes that (1) there are established risk factors and structural prerequisites for the development of heart failure; (2) therapies employed before left ventricular dysfunction or symptoms develop can reduce morbidity and mortality rates; (3) patients are expected to progress from one stage to the next unless slowed by treatment; and (4) all patients benefit from risk factor management including blood pressure control, lipid management, exercise, and smoking cessation. In this chapter, we focus primarily on stage C patients with reduced ejection fraction for whom there is a large base of evidence on which to guide therapy (Table 14–2). By contrast, a more limited discussion of empiric recommendations for patients with heart failure and normal ejection fraction is presented.

DIURETICS AND SODIUM RESTRICTION

Pathophysiologic Mechanisms

A common abnormality in patients with heart failure is an expanded extracellular volume that is characterized by pulmonary congestion, peripheral edema, ascites, elevated jugular venous pulse, and symptoms such as ankle swelling, dyspnea on exertion, and orthopnea. These abnormalities are related in part to avid sodium retention by the kidney, which is caused by a complex interaction among decreased cardiac output and renal perfusion, redistribution of intrarenal blood flow to the sodium conserving medulla, systemic and local neurohormonal activation, and increased renal sympathetic nerve activity.[8] Diuretics are a cornerstone in the pharmacologic management of patients with signs and symptoms related to an expanded extracellular volume. Although restriction of dietary sodium intake is universally recommended for patients with heart failure who are treated with diuretics, this recommendation is inadequately implemented in many clinical settings. The failure to correctly implement a sodium-restricted diet diminishes the effectiveness of diuretics, increases the dosage requirement, and aggravates potassium loss.

Sodium Restriction

There are few studies that specifically assess the effect of dietary sodium intake in heart failure. Cody and coworkers[9] studied 10 patients with severe heart failure who were monitored in a clinical research center after all vasodilator and diuretic therapy was discontinued during a diet containing a very low (approximately 200 mg/day) or a moderate (approximately 2000 mg/day) sodium intake. The very low-sodium diet was associated with a significant reduction in weight, in mean pulmonary artery pressure, and in mean pulmonary capillary wedge pressure. By contrast, a high-salt diet in patients with mild heart failure has been shown to increase left ventricular volumes, suppress renin and aldosterone concentrations, and reduce daily sodium excretion.[10] Thus, even in patients without signs or symptoms of congestion, there is a reduced ability to excrete a sodium load. Other studies in patients with hypertensive heart disease[11,12] and heart failure with preserved systolic function[13] suggest that sodium restriction may reduce natriuretic peptides, attenuate ventricular remodeling, and improve clinical status.

Table 14–3 High-Sodium Containing Foods

Food	Portion	Sodium (mg)
American cheese	1 oz	406
Tuna, canned	3 oz	288
Ham	3 oz	1114
Hot dog	1	639
Spaghetti, canned	8 oz	1124
Bread, white	1 slice	114
Corn chips	2 oz	462
Chicken noodle soup	1 cup	1107
Beans, canned	1 cup	326
Soy sauce	1 tbsp	1029
Italian dressing	1 tbsp	116
Big Mac	1	1010

The recommended level of sodium restriction depends on the history and severity of edema formation. In patients with asymptomatic left ventricular dysfunction, judicious sodium restriction to no more than 3500 mg/day is probably useful. Patients with mild heart failure typically require restriction to less than 2500 mg/day, whereas those with moderate-to-severe heart failure should reduce intake to less than 2000 mg/day. Important principles include substituting herbs and other spices for table salt, avoiding common foods that contain large amounts of sodium (Table 14–3), reading food labels carefully, and cooking with fresh meats and vegetables. Keys to compliance are patient and family education by nurse specialists, referral to nutritionists, and use of patient-oriented texts and websites (e.g., *www.hfsa.org*).[14]

DIURETICS

Mechanisms of Action

Diuretics inhibit sodium reabsorption in the kidney, thereby leading to increased urinary sodium and water excretion.[15] There are several available diuretics (Table 14–4) that are usually classified according to their site of action in the kidney. Thiazide diuretics inhibit the sodium-chloride symporter in the distal convoluted tubule where approximately 5% to 10% of the filtered load of sodium is reabsorbed. As cardiac function and renal perfusion decrease, proximal tubular sodium reabsorption increases to 80% to 90% of the filtered load, making thiazide diuretics less effective. Therefore, for most patients with heart failure and edema, a loop diuretic is the preferred initial agent. Loop diuretics inhibit the sodium-potassium-chloride symporter in the thick ascending limb of the loop of Henle, leading to a marked increase in the fractional excretion of sodium. In addition, loop diuretics inhibit solute concentration in the medullary interstitium, thereby

Table 14–4 Diuretic Therapy in Heart Failure

Generic Name	Usual Oral Dose	Duration of Action (h)
Loop Diuretics		
Furosemide	40-160 mg/day	6-8
Bumetanide	0.5-4 mg/day	4-6
Torsemide	5-20 mg/day	1-4
Ethacrynic acid	50-150 mg/day	6-8
Thiazide and Thiazide-Like Diuretics		
Chlorothiazide	500-1000 mg/day	6-12
Hydrochlorothiazide	50-100 mg/day	>12
Metolazone	2.5-10 mg/day	24-48
Chlorthalidone	100 mg/day	24
Indapamide	1.25-5 mg/day	24
Potassium-Retaining Diuretics		
Spironolactone	25-100 mg/day	3 days after starting
Triamterene	100-200 mg/day	12-16
Amiloride	5-10 mg/day	24

decreasing the driving force for water reabsorption in the collecting duct. Because both loop diuretics and thiazides also cause potassium excretion, adjunctive therapy with potassium-retaining diuretics that act in the distal tubule and collecting duct may be required to maintain normokalemia. For a detailed discussion of the pharmacology of diuretics, see Chapter 23 in HD7e.

Adverse Effects

Despite the wide acceptance of diuretics, they have a number of long-term adverse effects such as electrolyte depletion, neurohormonal activation, hypotension, and renal insufficiency. Chronic diuretic therapy can result in hypokalemia, hyponatremia, hypocalcemia, and hypomagnesemia, as well as metabolic alkalosis. Hypokalemia and hypomagnesemia are of particular concern because they can precipitate arrhythmias in patients with heart failure. In addition to electrolyte depletion, diuretics may cause an increase in uric acid levels and contribute to the development of gout. An adverse effect of diuretics that may be particularly important in patients with heart failure is activation of neurohormonal pathways.[16,17] The mechanisms by which diuretics stimulate renin and norepinephrine release have not been completely defined,[18] but there are three important pathophysiologic consequences. First, renin secretion will result in increased secretion of aldosterone, which will promote sodium retention. Second, increased vasoconstriction secondary to increased levels of angiotensin II and norepinephrine may have a positive feedback effect in which the increased impedance to ventricular emptying results in progressive ventricular dysfunction. Third, norepinephrine, angiotensin II, and aldosterone exert direct toxic effects on the myocardium, resulting in ventricular remodeling and proarrhythmia. Finally, neurohormonal activation is a strong predictor of increased mortality.[19,20] Therefore, it is possible, although unproven, that diuretic-associated neurohormonal stimulation could be associated with an adverse effect on long-term survival.

The association of diuretic therapy with neurohormonal activation has an important influence on the optimal use of diuretics for patients with heart failure. As discussed, it is useful to reinforce dietary sodium restriction in patients who appear to require large doses of diuretics. Second, it is important to emphasize that many of the adverse effects of neurohormonal stimulation by diuretics can be blocked by the concomitant administration of an ACE inhibitor and β-blocker. With combination therapy, the beneficial effect of diuretics may be obtained, but the increase in angiotensin II and aldosterone will be blocked and the effects of norepinephrine will be inhibited. It is also important to understand the effects of secondary processes that can cause overall sodium balance to return to neutral, despite continued diuretic administration. The response to a diuretic-induced reduction of extracellular volume is a further reduction in sodium and chloride excretion through stimulation of proximal tubular reabsorption, increased renal sympathetic nerve activity, and increased aldosterone.[21] Chronic diuretic treatment induces a number of changes in the collecting duct and distal tubule, including increases in mitochondrial volume and adenosine triphosphatase activity, and cellular hypertrophy, that increase distal tubular reabsorption.[22]

The pharmacokinetic and pharmacodynamic effects of diuretics may be abnormal in patients with heart failure.[15] In patients with bowel wall edema and splanchnic hypoperfusion, the absorption of orally administered drugs can be reduced, thereby delaying the time to appearance and peak concentration of the diuretic in the urine. Unless the glomerular filtration rate is less than 30 mL/min, the pharmacokinetics of intravenous formulations are largely normal in heart failure, which explains the effectiveness of the intravenous route in patients with decompensated heart failure (see Chapter 17). The pharmacodynamic response is reduced in heart failure, so that the rate of sodium excretion is reduced at any given renal tubule diuretic concentration.[15] Thus, the "ceiling" dose, or dose above which further sodium excretion is minimal, is typically double in patients with heart failure

compared with normal subjects. For this reason, prescribing a larger dose of diuretic is commonly more effective than increasing the frequency of administration.

Practical Considerations

Short-term studies have shown that diuretics reduce signs and symptoms of congestion and lower cardiac filling pressures within hours to days of initiation; intermediate-term studies demonstrate the beneficial effects of diuretics on exercise tolerance and quality of life. The effects of diuretics on morbidity and mortality rates in heart failure have not been tested. According to ACC/AHA guidelines, diuretics should be prescribed to all patients with current or prior symptoms of heart failure who have evidence of fluid retention, and should be combined with an ACE inhibitor and β-blocker to maintain clinical stability.[4] The first step is to identify patients with fluid retention based on symptoms (shortness of breath, orthopnea, paroxysmal nocturnal dyspnea), signs (rales, elevated jugular venous pulse, peripheral edema), and other clinical characteristics such as weight gain, frequent outpatient visits, or recurrent hospitalizations. Noninvasive studies that may be helpful in recognizing hypervolemia include chest radiography, natriuretic peptide levels, and echocardiography, although the sensitivity and specificity of these tests are limited.[23] Newer devices, such as implantable hemodynamic and intrathoracic impedance monitors[24,25] and noninvasive Valsalva response recorders,[26] have also been developed for use in heart failure. Direct assessment of blood volume using a radiolabeled albumin technique is available at specialized centers.[27] If the clinical evaluation is equivocal, a right heart catheterization to measure intracardiac filling pressures should be considered.

For patients with heart failure, the most commonly prescribed loop diuretic is furosemide, which is usually started at a low dose (20 to 40 mg once daily) and increased until urine output increases and weight loss occurs. The dose or frequency of diuretics may be titrated while monitoring several endpoints. Because one of the primary goals of therapy is symptom relief, the dose of diuretics may be reduced to maintenance levels once there are satisfactory reductions in dyspnea, orthopnea, and edema. Attention to normalizing the jugular venous pulse and eliminating congestive hepatomegaly is key to achieving euvolemia, especially in patients with advanced heart failure. The development of symptomatic hypotension or azotemia often necessitates holding diuretic therapy, but diuretics can often be resumed at a lower dose after adjustment of other heart failure medications such as ACE inhibitors and β-blockers. Once fluid retention has resolved, a maintenance dose of diuretics is recommended to prevent recurrent volume overload.[4] Select patients with mild heart failure or asymptomatic left ventricular dysfunction may not require maintenance diuretics if they were initially effective in reducing dietary sodium intake,[28] although a strategy of diuretic withdrawal has not been tested.

Some patients have refractory signs and symptoms of heart failure, and are labeled "diuretic resistant." These patients may be noncompliant with their medication regimens or unable to limit sodium and fluid intake; they require reinforcement of education. In patients with biventricular or right heart failure, significant bowel wall edema may limit oral absorption, so that intravenous formulations (e.g., furosemide or chlorothiazide) or loop diuretics with increased oral bioavailability (e.g., torsemide)[29] may be effective in initiating a diuresis. In patients with low cardiac output, the problem is inadequate sodium delivery to the tubular lumen caused by reduced renal perfusion and impaired tubular secretion of diuretics. Most patients will respond to a doubled dose rather than to the same dose taken twice daily.

In other patients, the combination of a loop diuretic with a thiazide diuretic or metolazone, which facilitates the action of the loop diuretic, may be particularly effective.[30] The mechanisms of diuretic synergism are not fully defined but are likely related to the fact that diuretics inhibit transport in different segments of the nephron. Adding a thiazide diuretic may inhibit "compensatory" distal tubular adaptations, and may result in a sustained diuresis that would be much greater than simply increasing the dose of the loop diuretic. The addition of metolazone may also be used for transient episodes of fluid accumulation. This strategy maintains the dose of the loop diuretic constant, minimizes errors associated with frequent dose changes, and reduces the long-term exposure to high-dose diuretics. Close monitoring is required because this "booster" pill strategy can lead rapidly to overdiuresis, hypokalemia, and renal insufficiency.

During long-term treatment, and particularly during changes in diuretic regimens, it is important to monitor levels of potassium, given the marked kaliuretic effects of diuretic drugs. Renal function, as assessed by serum blood urea nitrogen and creatinine levels, should be monitored because this parameter may be sensitive to changes in blood volume and/or vasoconstrictor hormones. Excessive volume depletion should be avoided because it may result in hypotension and renal dysfunction. In patients with coexistent heart failure and chronic kidney disease (so-called "cardiorenal syndrome"),[31] potential nephrotoxic agents should be used with extreme caution. Nonsteroidal anti-inflammatory drugs and cyclooxygenase-2 inhibitors should be avoided because these agents can inhibit the natriuretic effects of diuretics and impair renal function, thereby exacerbating fluid retention. Other agents such as thiazolidinediones[32] and pregabalin[33] that cause edema are relatively contraindicated in heart failure.

Patients should weigh themselves on a daily basis. If they do not own a scale, one should be provided for them. This process helps to engage patients in their medical care, alert them to the effect of dietary indiscretions, and facilitate "fine tuning" of medications. For select patients, electronic scales that transmit daily information on weight, vital signs, and symptoms may help to maintain accuracy and compliance. In the case of a rapid weight gain of 2 to 3 pounds, a temporary increase in diuretic dosage or the addition of metolazone or a thiazide diuretic for 1 to 3 days, is often sufficient to return the patient to "dry weight." In patients with advanced heart failure, it is important to remember that dry weight may decrease over time with loss of skeletal muscle mass and adipose tissue due to cardiac cachexia.[34] The use of intravenous diuretics and other fluid management strategies in hospitalized patients with decompensated heart failure are discussed in Chapter 17.

RENIN-ANGIOTENSIN SYSTEM INHIBITORS

Pathophysiologic Mechanisms

Nearly 30 years ago, an important advance in the treatment of heart failure was the recognition that pump function is critically dependent on the outflow resistance against which the ventricle must empty.[35] Acute hemodynamic studies established that vasodilator drugs that relax peripheral arterioles shift the ventricular function curve upward and to the left, resulting in an increase in cardiac output without a large change in blood pressure. Moreover, drugs that increase venous capacitance redistribute blood volume from the central to peripheral reservoirs and, therefore, decrease the signs and symptoms of elevated cardiac filling pressures. Unlike hydralazine, that acts predominantly on the arterioles leading to a reduction in impedance or nitrates that, in turn, act on arterial compliance and venous tone, ACE inhibitors have a balanced effect on arterioles, arteries, and veins.

The traditional view of ACE inhibitors was that their primary mechanism of action in heart failure was a reduction in angiotensin II-mediated vasoconstriction. The reduction of angiotensin II was noted to decrease the release of aldosterone from the adrenal gland and norepinephrine in the synaptic cleft.[36] Subsequent studies showed that the actions of ACE inhibitors are considerably more complex than a simple effect on circulating levels of angiotensin II (Fig. 14–2). Because kininase is identical to converting enzyme, ACE inhibitors also reduce the metabolism of bradykinin. Bradykinin can stimulate the release of nitric oxide and other endothelium-dependent vasodilators including prostaglandins. More importantly, by inhibiting tissue renin-angiotensin systems in blood vessels, the kidney, and the heart, ACE inhibitors play a critical role in attenuating vascular and myocardial remodeling, reducing inflammation and the risk of thrombosis, and delaying the progression of renal disease. All of these actions have an important impact on mediating the clinical efficacy of ACE inhibitors in heart failure.

Several nonenzymatic pathways independent of ACE exist for the conversion of angiotensin I to angiotensin II and may contribute to persistent availability of both circulating and tissue angiotensin despite treatment with ACE inhibitors (see Fig. 14–2).[36] This "escape" phenomenon may be due, in part, to non-ACE pathways of angiotensin I metabolism (e.g., myocardial chymase) and provides the rationale for the development of angiotensin receptor blockers.[37] The angiotensin receptor blockers bind competitively to, and dissociate slowly from, angiotensin II type 1 receptors.[38] Circulating angiotensin II levels increase during therapy due to loss of negative feedback. There are two angiotensin receptor blockers approved for the treatment of heart failure (Table 14–5). Valsartan is approved for the treatment of patients with NYHA functional class II-IV heart failure and indicated to reduce cardiovascular mortality in clinically stable patients with left ventricular failure or dysfunction following myocardial infarction. Candesartan is indicated to reduce the rate of cardiovascular mortality and the number of hospitalizations in patients with NYHA functional class II-IV heart failure and reduced ejection fraction.

Clinical Efficacy

ACE Inhibitors

Numerous prospective, placebo-controlled studies have shown the beneficial effects of ACE inhibitors on exercise tolerance, salt and water balance, clinical signs and symptoms, neurohormonal stimulation, quality of life, and survival in patients with chronic heart failure (Table 14–6). The concordance of findings in these multicenter trials provides a strong scientific basis for the use of ACE inhibitors in the management of heart failure. Several multicenter trials deserve comment.

Cooperative North Scandinavian Enalapril Survival Study (CONSENSUS)

CONSENSUS randomized 253 hospitalized patients with New York Heart Association (NYHA) functional class IV

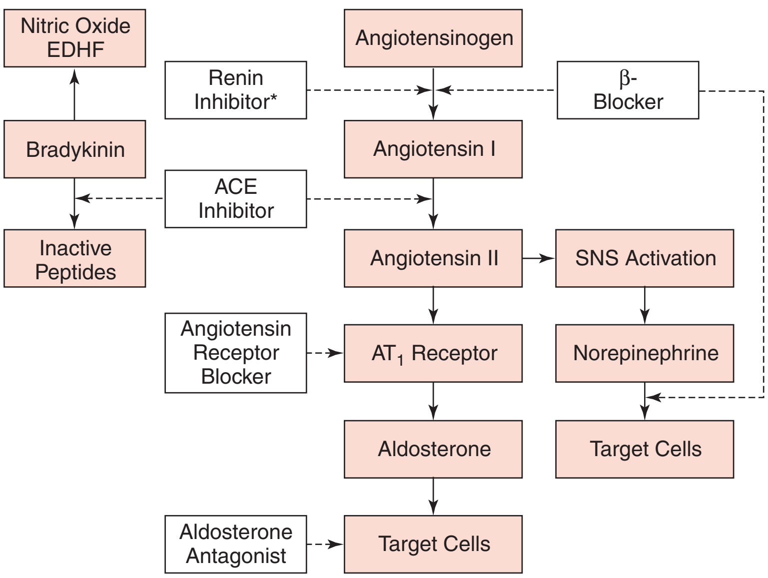

Figure 14–2 Pharmacologic agent (*open boxes*) used to manipulate the renin-angiotensin-aldosterone system (*shaded boxes*). *Dashed lines* signify inhibitory pathways. *Asterisk* denotes investigational agents. symptoms to either enalapril or placebo in addition to treatment with digoxin, diuretics, and non-ACE vasodilators.[39] Based on an interim analysis, enalapril was associated with a highly significant survival benefit compared with placebo (52% versus 36%), although there was no difference in the combined risk of death or hospitalization for heart failure. The CONSENSUS trial was prematurely terminated, because it was deemed unethical to continue a trial in which one half of the participants was randomized to placebo.

Vasodilator Heart Failure Trial (V-HeFT) II

V-HeFT I was the first placebo-controlled trial to demonstrate that vasodilators could prolong survival in patients with heart failure.[40] V-HeFT II was designed to compare treatment with hydralazine-isosorbide dinitrate, which was the superior drug combination in V-HeFT I, to enalapril, in patients with mild-to-moderate heart failure due to ischemic or nonischemic cardiomyopathy.[41] The enalapril group had a lower 2-year mortality rate compared with those patients randomized to hydralazine-isosorbide dinitrate (18% versus 25%; mortality reduction, 28%; P = 0.016). Interestingly, exercise time and left ventricular function improved to a greater degree in the patients randomized to hydralazine-isosorbide dinitrate.

Studies of Left Ventricular Dysfunction (SOLVD)

SOVLD was a prospective, double-blind, placebo-controlled trial in patients with an ejection fraction of 35% or less.[42] The SOLVD Treatment Trial randomized 2569 patients with NYHA functional class II or III heart failure, treated with digitalis and diuretics, to enalapril or placebo. After a mean follow-up of 41 months, there were significantly more deaths in the placebo group compared with the enalapril group (510 versus 452; mortality reduction, 16%; P = 0.0036). Furthermore, enalapril was associated with a 30% reduction in hospitalizations for heart failure.

The SOLVD Prevention Trial[43] was run concurrently with the Treatment Trial and used the same experimental design except for the restriction to patients with no or minimal symptoms of heart failure who were on no treatment for overt heart failure. After an average follow-up of 37 months, there were 334 deaths in the placebo group compared with 313 in the enalapril group. This 8% mortality reduction approached, but did not achieve, statistical significance (P = 0.30). More impressive were the highly significant reductions in the first hospitalization for heart failure (36%) and in the onset of heart failure requiring pharmacologic therapy (37%).

Assessment of Treatment with Lisinopril and Survival (ATLAS)

Despite controlled trials demonstrating the benefits of high-dose ACE inhibitor therapy (e.g., captopril 50 to 100 mg three times daily, enalapril 10 to 20 mg twice daily), much lower doses are used in clinical practice owing to concerns regarding patient tolerance. The ATLAS study[44] randomized 3164 patients with NYHA functional class II-IV heart failure and an ejection fraction of 30% or less to low-dose (2.5 to 5 mg daily) or high-dose (32.5 to 35 mg daily) lisinopril. After a median follow-up of 46 months, high-dose lisinopril was modestly superior in decreasing the combined risk of death or hospitalization (12% reduction, P = 0.0002), but had no significant effect on all-cause mortality. Dizziness and renal insufficiency were more common in the high-dose group, but the rate of

Table 14–5 ACE Inhibitor, Angiotensin Receptor Blocker and β-Blocker Therapy in Heart Failure with Low Ejection Fraction

Generic Name	Initial Daily Dose	Maximum Dose

drug withdrawal due to adverse effects (18%) was similar in the two groups.

Angiotensin Receptor Blockers

In early clinical studies in patients with chronic heart failure caused by left ventricular systolic dysfunction, angiotensin receptor blockade produced beneficial hemodynamic effects and was generally well tolerated.[45] The Evaluation of Losartan in the Elderly (ELITE) I study randomly assigned 722 patients aged 65 years or older with NYHA functional class II through IV heart failure and an ejection fraction of 40% or less to receive losartan or captopril for 48 weeks.[46] Although there was no difference between the drugs with regard to the primary safety endpoint (i.e., treatment effect on renal function), losartan unexpectedly decreased mortality by 46%. With a design similar to ELITE I, but powered to detect a difference in all-cause mortality, ELITE II randomized 3152 patients with mild-to-moderate heart failure to losartan (target dose 50 mg once daily) or captopril (target dose 50 mg three times daily) and demonstrated a nonsignificant 13% reduction in mortality in favor of captopril.[47,72] There were also trends in favor of ACE inhibitor therapy for the secondary endpoint of sudden cardiac death and the combined endpoint of death and hospitalization. Fewer patients randomized to losartan discontinued therapy due to side effects (9% versus 15%, $P < 0.001$). The inferiority of losartan in ELITE II was likely attributable to under-dosing. Although losartan is not approved for the treatment of heart failure, the recommended daily dose in this setting is 100 mg.

There is a theoretical reason to suggest that combined therapy with an angiotensin receptor blocker and an ACE inhibitor would be more clinically effective than therapy with either alone, and this thesis has been tested in several clinical trials. In one small study, 33 patients with NYHA functional class III to IV heart failure on maximally tolerated doses of ACE inhibitors were randomized to receive adjunctive therapy with placebo or losartan for 6 months.[48] The addition of losartan was associated with a lower NYHA class and higher peak exercise oxygen consumption. The Valsartan in Heart Failure Trial (Val-HeFT) randomized 5010 patients with NYHA functional class II-IV heart failure to receive valsartan (target dose 160 mg twice daily) or placebo in addition to usual therapy that included ACE inhibitors in 93% and β-blockers in 36%.[49] Valsartan significantly reduced the combined endpoint of mortality and morbidity by 13% ($P = 0.009$), including a 28% reduction in heart failure hospitalization, but exerted a neutral effect on all-cause mortality. Despite post-hoc analysis that raised concern about adverse outcomes in patients who received an ACE inhibitor, angiotensin receptor blocker and β-blocker (so-called "triple therapy"), the Candesartan in Heart failure: Assessment of Reduction in Mortality and morbidity (CHARM)-Added study reported similar efficacy results, as well as safety.[50] In

CHARM-Added, 2548 patients with mild-to-moderate heart failure and reduced ejection fraction who were being treated with ACE inhibitors were randomized to receive candesartan (target dose 32 mg once daily) or placebo. During a median follow-up of 41 months, candesartan reduced the combined endpoint of cardiovascular death or heart failure hospitalizations by 15% ($P = 0.01$). Importantly, candesartan reduced this risk in patients treated with β-blockers in addition to an ACE inhibitor, and was as effective among patients taking a recommended dose of ACE inhibitor as in those taking lower doses. The risks of worsening renal function and hyperkalemia were higher, however, with "add on" therapy.

For patients who are intolerant of ACE inhibition, angiotensin receptor blockade has proven effective as alternative therapy. In the CHARM-Alternative study, 2028 patients with symptomatic left ventricular dysfunction who were not receiving ACE inhibitors because of cough (72%), hypotension (13%), or renal dysfunction (12%) were randomized to receive candesartan (target dose 32 mg once daily) or placebo.[51] During a median follow-up period of 34 months, candesartan reduced the risk of cardiovascular death or heart failure hospitalization by 23% ($P = 0.004$). In addition, there was a trend toward a decrease in all-cause mortality with candesartan (hazard ratio, 0.87; 95% CI, 0.74 to 1.03; $P = 0.11$). A subgroup of 366 patients in the Val-HeFT study who were not taking ACE inhibitors at baseline also experienced a significant reduction in the rates of morbidity and mortality with angiotensin receptor blockade.[49]

In addition to targeting patients with heart failure, several large trials have studied the effects of ACE inhibitors and angiotensin receptor blockers on mortality in patients after acute myocardial infarction (see Table 14–6).[52] These trials focused on a patient population that is not comparable with patients with chronic heart failure and reduced ejection fraction who were enrolled in the V-HeFT, CONSENSUS, SOLVD, and CHARM trials. In addition, background drug therapy and study drug dosing differed significantly from the chronic heart failure trials. Nevertheless, the results of the post-infarction trials have several important implications when considering treatment for patients with left ventricular systolic dysfunction and/or heart failure.

First, the majority of these trials showed that treatment with an ACE inhibitor initiated early after myocardial infarction had a small but significant benefit in reducing short-term mortality. This finding is significant because most of the patients enrolled in the post-infarction trials did not have heart failure. Furthermore, the Heart Outcomes Prevention Evaluation (HOPE) study demonstrated a reduction in mortality from the ACE inhibitor, ramipril, in patients with atherosclerosis in the absence of heart failure,[53] and the European trial on Reduction Of cardiac events with Perindopril in stable coronary Artery disease (EUROPA) confirmed the vasculoprotective effect of ACE inhibitors in even lower risk patients.[54]

A second and more compelling issue is that early intervention with an ACE inhibitor can prevent, or at least delay, the onset of heart failure. In the SAVE trial[218] captopril was associated with a 37% reduction in the development of heart failure and a 22% reduction in hospitalizations for heart failure. In CONSENSUS II, enalapril reduced the need to change therapy for heart failure by 10%,[55] and in the Survival of Myocardial Infarction Long-term Evaluation (SMILE) study, early use of zofenopril reduced the likelihood of developing severe heart failure within 6 weeks of the infarction.[56] These data are consistent with the results of the SOLVD Prevention Trial, wherein a 20% reduction in hospitalizations for heart failure and a 29% reduction in the development of heart failure were found. In the HOPE study, ramipril reduced the risk of developing heart failure by 23%; and in EUROPA, perindopril reduced heart failure hospitalizations by 39%. These cumulative data suggest that ACE inhibitors have a significant clinical benefit, even in relatively low-risk patients.

Third, results from the Valsartan in Acute Myocardial Infarction (VALIANT) trial[57] suggest that, although ACE inhibitors and angiotensin receptor blockers are equally effective at reducing the rates of morbidity and mortality in patients with acute myocardial infarction and heart failure, left ventricular systolic dysfunction or both, combined therapy offers no advantages over ACE inhibition or angiotensin receptor blockade alone and increases the rate of adverse events.[57] These findings appear to be at odds with results from the Val-HeFT and CHARM studies demonstrating further cardiovascular risk reduction with the addition of angiotensin receptor blockade to background ACE inhibition. However, differences in patient population, drug regimens, and patterns of cardiovascular risk among patients with stable heart failure and those with acute myocardial infarction likely explain these divergent results.[57]

Practical Considerations

ACE Inhibitors

Despite the overwhelming database from clinical trials and the adoption of consensus guidelines, the application (including usage and dosing) of ACE inhibitors to the broad population of patients with chronic heart failure remains suboptimal. Several factors are responsible for this. First, the use of ACE inhibitors appears to vary among different specialties, as evidenced by the fact that cardiologists are more likely to prescribe ACE inhibitors than are primary care physicians.[58] Second, it is a common perception that ACE inhibitors are associated with a high frequency of adverse effects when used at higher doses and/or in the elderly. However, the early experience from CONSENSUS and SOLVD in a large population of ambulatory patients suggested that the incidence of these complications is acceptably low, given the potential benefit, and ATLAS demonstrated no increased risk of drug withdrawal with high-dose therapy.[44] The management and avoidance of ACE inhibitor-related complications can be facilitated by the knowledge of certain predisposing factors and by the institution of precautionary measures. Other patient-related factors associated with physician underuse of ACE inhibitors include older age, renal dysfunction, and preserved systolic function.[59]

The most important adverse effect to monitor during the initiation of ACE inhibitors is hypotension (Table 14–7), although the decrease in blood pressure is usually minor and the patient is asymptomatic. Patients who are at highest risk for symptomatic hypotension are those who are volume depleted, receiving high doses of diuretics or concomitant vasodilator therapy, or older than 75 years. Patients with increased activation of the renin-angiotensin-aldosterone

Table 14–7 Adverse Effects of Renin-Angiotensin-Aldosterone System Inhibitors

ACE, angiotensin-converting enzyme.

system, manifest by increased levels of plasma renin activity, are those who have angiotensin-mediated vasoconstriction and who are also at risk for hypotension.[60] Because measurements of plasma renin activity are not readily available, clinicians can take advantage of the relatively tight inverse correlation between plasma renin activity and serum sodium.[61] Patients with a low serum sodium (<130 mmol/L) are more likely to develop hypotension during the initiation of therapy. Useful strategies in these patients include temporary withholding of diuretics, liberalizing salt intake, and the use of a test dose of a short-acting ACE inhibitor (e.g., captopril 6.25 mg) followed by gradual upward titration over several weeks. If symptomatic hypotension occurs with the first dose, it may not recur with subsequent dosing.

Although mild renal insufficiency may concern clinicians, there are several misconceptions regarding the effects of ACE inhibitors on renal function. Many patients with heart failure actually have an improvement in renal function with the initiation of ACE inhibitors, likely mediated by an increase in cardiac output and renal perfusion. In addition, the incidence and magnitude of renal insufficiency in controlled trials are low, and only a small percentage of patients (less than 0.5%) are withdrawn from therapy. The mechanisms that contribute to renal insufficiency are complex and are accentuated by concomitant drug therapy and hemodynamic abnormalities. Patients at risk for renal insufficiency share many of the same features as those at risk for hypotension. In general, patients should be reassessed approximately 1 week after initiation of an ACE inhibitor to monitor renal function and blood pressure. If there is an increase in serum creatinine of 0.5 mg/dL or more, the volume status and diuretic dose should be reassessed. In the majority of cases, renal function will return to baseline once volume status returns to normal or if the diuretic dose is decreased. It is also advisable to check for concomitant medications (e.g., nonsteroidal anti-inflammatory drugs) or medical conditions (e.g., renal artery stenosis) that can aggravate renal insufficiency. Despite these concerns, ACE inhibitors may slow the progression of renal disease in heart failure patients with hypertensive and/or diabetic nephropathy.[62]

Hyperkalemia can occur in patients receiving ACE inhibitors because of the reduction in angiotensin II-mediated aldosterone secretion. Elevated potassium levels are more common in patients with diabetes or chronic kidney disease, especially if they are receiving potassium supplements or potassium-retaining diuretics. Therefore, the dosage of potassium chloride and potassium levels should be monitored approximately 1 week after initiating ACE inhibitors, and potassium-retaining diuretics should be used with caution.

The other side effects of ACE inhibitors, such as dysgeusia, skin rash, and cough, are commonly self limited or reversible with discontinuation of the drug. Clinicians must be particularly cautious about stopping ACE inhibitors because of cough, which has been reported in 5% to 15% of patients in clinical studies. ACE inhibitor-related cough is typically nonproductive, arises during the first few months of therapy, and disappears within 7 to 10 days of drug withdrawal. However, cough is a common manifestation of heart failure and may respond to an increased dose of diuretics, ACE inhibitor, or both. If the cough is intolerable, a smaller dose or temporary discontinuation can be tried. In the past, many patients would tolerate a mild cough in exchange for the important improvements in survival and quality of life; however, most patients can be easily switched to an angiotensin receptor blocker with expected clinical benefits.[51]

Angioedema is a rare but potentially life-threatening complication of ACE inhibitor therapy that can occur weeks to months after drug initiation. The causal mechanism is believed to be an accumulation of bradykinin or one of its metabolites. An ACE inhibitor should not be prescribed to any patient with a history of angioedema. Furthermore, if a patient develops angioedema while taking an ACE inhibitor, the drug should be stopped immediately.

Doses of ACE inhibitors should be titrated upward over several weeks until target doses (e.g., doses that have been shown to reduce the morbidity and mortality rates in clinical trials) are achieved (see Table 14–5). The issue of the optimal dose has been controversial because it is a common impression that many patients are being treated with substantially lower doses.[63] Although results from the ATLAS study[44] argue in favor of trying to achieve high-dose ACE inhibitor therapy to reduce the risk of hospitalization, lower doses showed similar effects on symptoms and mortality. For patients who cannot tolerate high-dose ACE inhibitors, low or intermediate doses should be continued while β-blockers are initiated. Once a maximally tolerated dose of ACE inhibitor has been achieved, patients can generally be maintained on this dose long term despite changes in other heart failure medications. However, 20% to 25% of patients with advanced heart failure will develop a circulatory or renal limitation to ACE inhibitor therapy.[64] These patients tend to be older with longer duration of heart failure, lower blood pressure, and baseline renal dysfunction. ACE inhibitor intolerance is a marker of poor prognosis.

Another controversial issue is whether the beneficial effects of ACE inhibitors are class or drug specific. Currently, captopril, enalapril, lisinopril, quinapril, and fosinopril are indicated for the treatment of symptomatic heart failure. Captopril, ramipril, and trandolapril are indicated for post-myocardial infarction patients, and enalapril is the only ACE inhibitor indicated for the prevention of heart failure in asymptomatic patients. There are insufficient data to prove that the benefits demonstrated in clinical trials are applicable to all ACE inhibitors or only to the specific drug studied, but meta-analyses suggest an equivalent survival benefit for several different ACE inhibitors,[65] with consistent effects in a broad range of patients.[66] Although there are some differences in structure, pharmacokinetics, and pharmacodynamics, it is not known whether these differences have a significant impact on clinical outcomes. Furthermore, cost has become a dominant issue for many patients and providers.

There is some evidence that aspirin may attenuate the clinical benefits of ACE inhibitors by inhibiting bradykinin-mediated prostaglandin synthesis. In small pilot studies, aspirin inhibited the improvement in exercise duration and peak oxygen consumption and attenuated the hemodynamic effects of ACE inhibitors in patients with chronic heart failure.[67] Additional data from thromboembolic prevention studies also suggests that aspirin may have an adverse effect on the risk of heart failure hospitalizations.[68,69] Finally, in a post-hoc analysis of SOLVD, the survival benefit of enalapril was not seen in patients receiving antiplatelet therapy at baseline.[70] Notably, the attenuation of ACE inhibitor benefit appears less evident with clopidogrel. Current guidelines recommend aspirin use for primary and secondary prevention of myocardial infarction in patients with ischemic heart failure, yet there is no proven role for aspirin in patients with nonischemic cardiomyopathy.[68]

Angiotensin Receptor Blockers

Based on the clinical trials data and the ACC/AHA guidelines,[4] there are several indications for angiotensin receptor blockers in patients with heart failure and reduced ejection fraction. First, these agents may be used as alternative therapy in patients who are intolerant to ACE inhibitors, primarily evidenced by persistent cough. Although angiotensin receptor blockers were initially believed to be a safe alternative in patients with ACE inhibitor-induced angioedema, case reports suggest that life-threatening events may recur with the use of these agents.[71] Second, although ACE inhibitors remain the initial agents of choice for inhibition of the renin-angiotensin system, angiotensin receptor blockers are a reasonable alternative and may be better tolerated in older patients,[72] although more recent data suggest that these agents are just as likely to produce hypotension and worsening renal function as are ACE inhibitors (see Table 14–7). Based on data from Val-HeFT and CHARM-Added, the addition of an angiotensin receptor blocker should be considered to reduce heart failure hospitalizations in patients who remain symptomatic despite ACE inhibitor and β-blocker therapy. The safety of adding an angiotensin receptor blocker to patients who are already treated with both an ACE inhibitor and aldosterone antagonist is unknown.

Like ACE inhibitors, angiotensin receptor blockers should be started at low doses (see Table 14–5) and titrated upward until target doses are achieved (e.g., candesartan 32 mg once daily, losartan 50 to 100 mg once daily, valsartan 160 mg twice daily). There have been no large studies comparing efficacy and safety of high- with low-dose angiotensin receptor blockade. The risks of hypotension, renal insufficiency, and hyperkalemia are similar to those seen with ACE inhibitor monotherapy, and the guidelines regarding clinical and laboratory follow-up discussed earlier should be followed. Greater caution is warranted when angiotensin receptor blockers are added to ACE inhibitors as shown by the higher rates of adverse events that required drug withdrawal in the combined therapy group in the VALIANT study.[57]

β-BLOCKERS

Pathophysiological Rationale

β-Blockers were traditionally contraindicated in patients with heart failure owing to concerns that their negative inotropic actions could result in clinically important deterioration. It is now well established that chronic overactivity of the sympathetic nervous system plays an important role in the pathophysiology of heart failure (discussed in detail in Chapter 21 in HD7e).[73] Adverse effects of circulating catecholamines and increased cardiac adrenergic drive include (1) myocardial hypertrophy, fibrosis, and apoptosis leading to ventricular remodeling and impaired contractile function; (2) β-receptor *downregulation*, a complex sequence of biochemical and molecular events resulting in a decreased number of surface β-receptors and uncoupling of the β-receptor complex; (3) atrial and ventricular arrhythmias; (4) myocardial ischemia; (5) impaired renal sodium excretion; and (6) peripheral vasoconstriction. Regardless of the mechanism, it is clear that β-blockers cause slowing or regression of ventricular remodeling, and in doing so reduce the rate of morbidity and mortality in patients with chronic heart failure.

Pharmacology

Three classes of β-blockers are available for clinical use (see Chapters 2 and 5, and Table 23–11 in HD7e). *First-generation* agents, such as propranolol and timolol, are non-selective β-blockers with an equal affinity for β_1- and β_2-receptors. *Second-generation* β-blockers, such as metoprolol and bisoprolol, selectively inhibit β_1-receptors. *Third-generation* agents, such as carvedilol and bucindolol, were developed to include other pharmacologic properties in addition to β-blockade, in particular, vasodilation. Carvedilol is a non-selective β_1/β_2-blocker with potent α_1-blocking properties. In vitro studies also suggest that carvedilol exerts antioxidant effects,[74] although the clinical relevance of these findings remains unknown. Bucindolol is also a nonselective β-blocker with weak vasodilator properties, probably mediated via α_1-receptor blockade.[73] Nebivolol is a β_1-blocker with vasodilatory properties related to increased bioavailability of nitric oxide.[75]

Clinical Efficacy

In 1975, investigators at the University of Göteberg in Sweden first reported the beneficial effects of β-blockers, when added

to digoxin and diuretics, in patients with dilated cardiomyopathy.[76] In the 1980s and early 1990s, several small clinical trials showed that β-blockers, when administered carefully, can result in improved ventricular structure and function, hemodynamics, and β-receptor density.[77] Subsequent studies also demonstrated benefits of β-blockade on exercise tolerance and symptoms in patients with mild-to-moderate heart failure.[78] Finally, randomized controlled trials involving more than 20,000 patients with reduced ejection fraction treated with ACE inhibitors and diuretics (Table 14–8) demonstrated conclusively that β-blockers reduce hospitalizations and prolong survival in patients with chronic heart failure. As with ACE inhibitors, subgroup and meta-analyses show that β-blockers are equally effective in patients with ischemic and nonischemic heart failure, and in a broad range of patients including women, diabetics, blacks, and the elderly.[66,79,80] Several multicenter trials deserve comment.

Cardiac Insufficiency Bisoprolol Study (CIBIS) I and II

CIBIS I randomized 641 patients with ischemic or nonischemic cardiomyopathy and moderate-to-severe heart failure to either bisoprolol (up to 5 mg daily) or placebo.[81] After an average follow-up of 23 months, the total mortality rate was slightly but not significantly reduced in the bisoprolol group (17% versus 21%, $P = 0.22$). Subgroup analysis demonstrated that the mortality benefit was confined to patients with nonischemic cardiomyopathy. CIBIS II randomized 2647 patients with NYHA functional class III-IV heart failure and

an ejection fraction of 35% or less to bisoprolol (up to 10 mg daily) or placebo for a mean of 1.3 years.[82] The study was stopped 18 months early because bisoprolol was associated with a 34% reduction in all-cause mortality. Bisoprolol also reduced sudden death by 44% and hospitalizations by 20%. Unlike CIBIS I, the treatment effects in CIBIS II were independent of the cause of heart failure. Notably, over 90% of the patients enrolled in CIBIS II were in NYHA class III and the annualized placebo mortality was only 13%, leading the investigators to warn against extrapolating the results to patents with severe heart failure.

U.S. Carvedilol Heart Failure Trials

The U.S. Carvedilol Heart Failure Trials program enrolled 1094 patients with NYHA functional Class II-IV heart failure and an ejection fraction of 35% or less, on ACE inhibitors and diuretics, into one of four trials based on the distance walked in 6 minutes. The Prospective Randomized Evaluation of Carvedilol on Symptoms and Exercise (PRECISE) study randomized 278 patients with moderate-to-severe heart failure to carvedilol or placebo for 6 to 8 months.[83] Carvedilol had no effect on the primary endpoint of exercise tolerance, but reduced the combined endpoint of death or cardiovascular hospitalizations by 37%. The Multicenter Oral Carvedilol in Heart Failure Assessment (MOCHA) trial randomized 345 patients with moderate-to-severe heart failure to one of three doses of carvedilol (12.5, 25, or 50 mg daily) or placebo.[84] As in PRECISE, treatment with carvedilol had no effect on exercise tolerance but reduced cardiovascular hospitalizations by 45% and all-cause mortality by 73%. The Mild Carvedilol Heart Failure study randomized 366 patients to carvedilol (50 to 100 mg daily) or placebo for up to 12 months.[85] Carvedilol reduced the risk of clinical progression—defined as death, heart failure hospitalization, or an increase in medications—by 48%, and all-cause mortality by 77%. In the severe heart failure study, carvedilol had no effect on the primary endpoint (quality of life), but improved global assessment by physicians and patients and increased ejection fraction.[86]

The U.S. Carvedilol Heart Failure Trials program was stopped prematurely by the Data and Safety Monitoring Board after a median follow-up of only 6.5 months because of a significant mortality benefit of carvedilol compared with placebo (risk reduction, 65%; P <0.0001).[87] Although the survival data were not considered conclusive because of the short follow-up period and small number of deaths (a total of 53), the combined results of the U.S. program led the U.S. Food and Drug Administration to approve carvedilol in 1997 for the treatment of patients with mild-to-moderate heart failure.

Metoprolol CR/XL Randomised Intervention Trial in Congestive Heart Failure (MERIT-HF)

MERIT-HF enrolled 3991 patients with predominantly mild-to-moderate heart failure and an ejection fraction of 40% or less into a randomized placebo-controlled study of sustained release metoprolol (up to 200 mg daily).[88] After a mean follow-up of 1 year, an independent safety committee recommended early termination of the study owing to a 34% lower risk of death in the metoprolol CR/XL group. In addition, metoprolol CR/XL reduced sudden deaths (by 41%), deaths due to worsening heart failure (by 49%), and total hospitalizations, and improved NYHA functional class and quality of life.[89] A post-hoc analysis of MERIT-HF and pooled data from other randomized controlled trials showed that these benefits extend to women, including women with clinically stable severe heart failure.[90]

β-Blocker Evaluation and Survival Trial (BEST)

BEST randomized 2708 patients with moderate-to-severe heart failure to placebo or bucindolol and demonstrated a nonsignificant 10% reduction in total mortality (P = 0.10).[91] Preliminary subgroup analyses suggested that patients with NYHA functional class IV symptoms and black patients tended to have worse outcomes on bucindolol therapy. The lower mortality benefit seen in BEST, when compared with MERIT-HF or CIBIS II, may be related to the population studied, the unique pharmacologic profile of bucindolol, or both.

Carvedilol Prospective Randomized Cumulative Survival Trial (COPERNICUS)

COPERNICUS was designed to test the efficacy of β-blockers in patients with severe heart failure.[92] COPERNICUS randomized 2289 patients with symptoms of heart failure at rest or on minimal exertion, who were clinically euvolemic, and who had an ejection fraction of less than 25%, to carvedilol or placebo. Patients could be enrolled during a heart failure hospitalization, but were excluded from participation if they required intensive care or were receiving intravenous vasoactive therapy. The trial was stopped early (mean follow-up, 10 months) by the Data and Safety Monitoring Board based on the finding of a 35% decrease in the risk of death with carvedilol. In addition, carvedilol decreased the combined risk of death or heart failure hospitalization by 31%.[93] The favorable effects of carvedilol were seen in all subgroups, including the highest-risk patients with recent or recurrent cardiac decompensation or ejection fraction of less than 20%.

Carvedilol and Metoprolol European Trial (COMET)

Given the proven benefits of carvedilol and sustained-release metoprolol relative to placebo, European investigators sought to compare the effects of carvedilol and metoprolol on clinical outcomes in heart failure. COMET randomized 3029 patients with NYHA functional class II-IV heart failure and an ejection fraction of less than 35% to receive carvedilol (target dose 25 mg twice daily) or immediate release metoprolol tartrate (target dose 50 mg twice daily).[94] After a mean follow-up of 58 months, all-cause mortality was 34% for carvedilol and 40% for metoprolol (hazard ratio, 0.83; 95% CI, 0.74 to 0.93; P = 0.0017), with the mortality benefit becoming apparent at about 6 months. Mean maintenance doses of carvedilol and metoprolol were 42 and 85 mg, respectively, with carvedilol exerting slightly greater blood pressure and heart rate lowering effects. The pattern of adverse events usually associated with β-blockade, including bradycardia and hypotension, was similar in the two groups.

Carvedilol Post-Infarct Survival Control in Left Ventricular Dysfunction (CAPRICORN)

The beneficial effects of β-blockers on survival after acute myocardial infarction were first shown in low-risk patients before the introduction of ACE inhibitors and thrombolysis. To determine the contemporary role of β-blocker therapy in higher risk patients, CAPRICORN randomly assigned 1959 patients with an ejection fraction of 40% or less within 3 to 21 days after acute myocardial infarction to receive carvedilol

or placebo.[223] Although there was no difference in the primary combined endpoint of death or cardiovascular hospitalization, all-cause mortality was significantly reduced by carvedilol (hazard ratio, 0.77; 95% CI, 0.60-0.98; P = 0.03).

Practical Considerations

Based on the results of controlled clinical trials, it is recommended that all stable patients with current or earlier symptoms of heart failure and reduced ejection fraction should be treated with a β-blocker unless contraindicated or not tolerated. Treatment with a β-blocker should be initiated as soon as left ventricular dysfunction is diagnosed and should not be delayed until the patient fails treatment with other drugs (e.g., ACE inhibitors and diuretics). Patients with minimally symptomatic or asymptomatic left ventricular dysfunction should also receive β-blockers to attenuate ventricular remodeling, to slow disease progression, and to reduce the risk of sudden death. Whether β-blockers are safe and effective in patients with refractory heart failure remains unknown, although data from COPERNICUS suggest that the risk of clinical deterioration may be overstated.[93] In addition, the Initiation Management Predischarge: Process for Assessment of Carvedilol Therapy in Heart Failure (IMPACT-HF) trial demonstrated that initiation of β-blocker therapy before hospital discharge in stabilized patients is safe, does not increase length of stay, and improves the long-term use of β-blockers.[95]

When beginning therapy with β-blockers, patients should be stable on background therapy consisting of ACE inhibitors and diuretics, with or without digoxin, although they do not need to be taking high doses of ACE inhibitors. There should be no or minimal fluid retention, and patients should not be hospitalized in an intensive care unit or have received positive inotropic therapy for decompensated heart failure. Volume depletion should also be corrected before initiating therapy. β-Blockers are relatively contraindicated in patients with reactive airway disease and in patients with severe bradycardia or conduction system disease that is not treated with a pacemaker. β-Blockers should be used with caution in patients with asymptomatic hypotension (e.g., systolic blood pressure <90 mm Hg). Although there is a theoretical concern that β-blockers may mask signs of hypoglycemia in the setting of diabetes, diabetic patients were not excluded from clinical trials. Furthermore, carvedilol was shown to have favorable metabolic effects and may delay the progression to microalbuminuria in patients with type 2 diabetes mellitus and hypertension.[96]

β-Blockers should be initiated at very low doses (e.g., bisoprolol 1.25 mg once daily, carvedilol 3.125 mg twice daily, metoprolol XL 12.5 to 25 mg once daily) and titrated slowly over several weeks as tolerated (see Table 14–5). During the titration phase, patients should be monitored closely for the development of adverse drug effects, including hypotension, worsening heart failure, or bradycardia. Family members should also be educated about potential side effects and how to monitor for drug intolerance. Hypotension is the most common side effect associated with β-blockers, especially with agents with concomitant α_1-blockade (e.g., carvedilol) and in the setting of volume depletion. Typically, patients describe mild lightheadedness, dizziness, or blurred vision, which resolves after a few doses, but syncope may occur. Strategies for managing hypotensive symptoms include taking β-blockers with food to slow absorption, staggering or reducing the doses of other vasodilators (e.g., ACE inhibitors), or reducing diuretic therapy. If symptoms persist, the dose of β-blocker should be decreased; abrupt withdrawal should be avoided.

Because the failing heart is dependent on adrenergic support, clinical heart failure status may worsen during the initiation of β-blocker therapy.[97] Although fluid retention and fatigue are less common than symptoms associated with hypotension, they are more likely to lead to β-blocker withdrawal.[87] Fluid retention, which may manifest as pulmonary and systemic venous congestion, can usually be managed with an increase in oral diuretics, whereas fatigue may require a decrease in the β-blocker dose. The management of acute decompensated heart failure in the setting of β-blocker initiation is discussed in Chapter 17. Another cause for hypotension or fatigue in patients recently started on β-blockers is bradycardia or heart block. Initial management includes assessing for laboratory or electrocardiographic evidence of digoxin toxicity and lowering the dose of β-blocker. If other medications with negative chronotropic effects are contributing (e.g., amiodarone, antidepressants), they should be stopped or permanent pacing should be considered. The role of right ventricular or biventricular pacing to allow for β-blockade, especially in mildly symptomatic or asymptomatic patients, is unknown.

Given the possibility of adverse effects occurring during initiation of β-blockers, upward titration should not occur until the patient is stable on the current dose. Overall, 10% to 15% of patients will not tolerate long-term therapy with β-blockers, although this rate may be higher in patients with more advanced disease[86] and in the elderly.[98] The optimal dosing of β-blockers in patients with heart failure is not known. In the MOCHA trial, in which patients were randomized to three different doses of carvedilol, there were trends toward a dose-dependent increase in ejection fraction and a decrease in mortality rates.[84] However, even patients randomized to low-dose carvedilol received significant clinical benefits. Similar clinical efficacy of low-dose versus high-dose metoprolol CR/XL was seen in MERIT-HF.[99] Therefore, although an attempt should be made to titrate β-blockers to the target doses used in controlled clinical trials (see Table 14–5), low-dose β-blocker therapy is preferred to no therapy. Patients should be advised that the clinical benefits of β-blockers may not become apparent for weeks to months, that they may feel worse before they feel better, and that the primary goals of therapy are to slow disease progression and prolong survival.

Choice of β-Blocker

Three β-blockers prolong survival and are approved by the U.S. Food and Drug Administration for the treatment of heart failure: bisoprolol, sustained-release metoprolol, and carvedilol. Nebivolol prolonged the time to death or hospitalization in elderly heart failure subjects,[98] but is not available in the United States. There are no controlled data on the use of atenolol in heart failure. Although some remodeling[100] and survival data[94] suggest that carvedilol is superior to metoprolol, these studies were flawed by the use of immediate-release metoprolol at a lower β_1-blocking dose. No studies have directly compared sustained-release metoprolol with

carvedilol at target doses, but review of the COPERNICUS and MERIT-HF studies suggests a similar reduction in all-cause mortality and sudden death. Metoprolol CR/XL may be preferred in patients with reactive airway disease or in whom compliance or cost is an issue. Carvedilol may be more effective at lowering blood pressure in hypertensive patients and improving insulin sensitivity in diabetics.[96] Carvedilol has also been shown to be safe and effective in stable patients with severe heart failure.[92]

OPTIONS FOR PATIENTS WHO REMAIN SYMPTOMATIC DESPITE STANDARD THERAPY

Patients who have persistent signs and symptoms of heart failure despite intensive treatment with diuretics, ACE inhibitors or angiotensin receptor blockers, and β-blockers present a difficult challenge for physicians who are treating patients with heart failure. Several pharmacologic, device, and surgical options are currently available and may require consultation with a heart failure specialist to optimize therapy for the individual patient. For patients with symptomatic heart failure, aldosterone antagonists and digoxin should be considered as adjunctive therapy to reduce the rates of morbidity and mortality that are related to progressive left ventricular failure. The combination of hydralazine and isosorbide dinitrate is indicated in black patients with moderate-to-severe heart failure and reduced ejection fraction. For patients with advanced or refractory heart failure, there are several options that can be considered individually or in combination (Table 14–9). Some patients will require multiple diuretics (e.g., loop and thiazide diuretics) or multiple vasoactive agents (e.g., combination of ACE inhibitors, angiotensin receptor blockers, and/or isosorbide dinitrate). A small number of selected patients may be candidates for ultrafiltration, mechanical circulatory support, and/or cardiac transplantation (see Chapter 18 and Appendix 3).

Cardiac resynchronization therapy improves contractile performance acutely in patients with dilated cardiomyopathy and intraventricular conduction delay and reduces the rates of morbidity and mortality in chronic heart failure (see Chapter 15). High-risk coronary artery bypass grafting and newer cardiac surgical procedures such as left ventricular reconstructive surgery and mitral valvuloplasty may reduce wall stress and cause reverse ventricular remodeling in patients with ischemic or nonischemic cardiomyopathy (see Chapter 16). However, these procedures have not been shown to prolong survival compared with medical therapy[101] and are limited to specialized centers. Continuous infusions of positive inotropic agents may be used as palliative care to bridge patients to end of life, or in selected patients as a bridge to cardiac transplantation. The subsequent discussion will focus on adjunctive pharmacologic therapy.

DIGOXIN

Pharmacologic and Clinical Effects

The mechanisms of action and the pharmacology of digoxin are discussed in Chapter 23 in HD7e and in other reviews.[102,103] Through its inhibition of sodium-potassium adenosine triphosphatase, digoxin affects cellular processes in the heart (increased cardiac contractility), vagal afferents (decreased sympathetic outflow), and kidney (decreased renin secretion) that contribute to its cardiovascular effects. Although digoxin has been commonly used in the management of heart failure, there was considerable controversy regarding the precise documentation of its clinical efficacy. Early studies were conflicting and interpretation was difficult because of small sample sizes and dependence on less precise clinical measures. Data from larger and more conclusive randomized controlled trials[104-108] have provided the scientific data to recommend the use of digoxin to decrease hospitalizations for heart failure in patients with reduced ejection fraction and current or earlier symptoms of heart failure.[4]

Many of the early trials that evaluated the efficacy of digoxin used a crossover design and sample sizes that are considered small in comparison with later multicenter trials. Subsequent trials used a parallel design in which digoxin was compared with placebo and other inotropic and/or vasodilator agents, including xamoterol, captopril, milrinone, and ibopamine. The German and Austrian Xamoterol Study Group randomized 433 patients to either placebo, digoxin, or xamoterol, a mixed β-agonist with some β-blocker activity.[104] Digoxin and xamoterol decreased symptoms of heart failure compared with placebo. The Captopril Digoxin Multicenter Research group randomized 300 patients to either placebo, digoxin, or captopril.[105] At 6 months, digoxin increased ejection fraction and reduced hospitalizations for heart failure, whereas captopril improved exercise duration and NYHA functional class. In other trials comparing digoxin with oral inotropic therapy, digoxin decreased neurohormonal activation and markedly decreased the frequency of clinical decompensation.[106,107] Two trials examined the effect of withdrawal

Table 14–9 Therapeutic Options for Patients with Advanced or Refractory Heart Failure

Approved	Investigational
Combination diuretics	Vasopressin receptor antagonists
Additional vasodilators	Adenosine receptor antagonists
Positive inotropic agents	Phosphodiesterase type 5 inhibitors
Cardiac resynchronization therapy	Intermittent natriuretic peptide infusions
Mechanical circulatory support	Erythropoietic agents
Cardiac transplantation	Enhanced external counterpulsation
Left ventricular reconstructive surgery	Implantable hemodynamic monitor
Surgical mitral valvuloplasty	Percutaneous mitral valvuloplasty
Intrathoracic impedance monitor	

of digoxin in heart failure patients who were treated with a diuretic only,[109] or with a diuretic and an ACE inhibitor.[110] In both trials, the withdrawal of digoxin resulted in a decrease in exercise tolerance, worsening heart failure symptoms, and lower ejection fraction.

Although these studies demonstrated the beneficial effects of digoxin on clinical endpoints, virtually all of these trials were unable to assess an effect on survival because of inadequate sample size. In addition, retrospective data in patients after acute myocardial infarction suggested that digoxin increased mortality.[111] The effect of digoxin on mortality in patients with chronic heart failure was assessed in the Digitalis Investigation Group (DIG) trial.[108] In the DIG trial, 6800 patients with mild-to-moderate heart failure and an ejection fraction of 45% or less were randomized to digoxin or placebo in addition to diuretics and ACE inhibitors. After a mean follow-up of 37 months, there were 1181 deaths in the digoxin group and 1194 deaths in the placebo group (risk reduction, 0.99; $P = 0.80$). Digoxin reduced the risk of death or hospitalization due to worsening heart failure, but tended to increase the risk of death due to other causes.

The cumulative data from controlled trials suggest that digoxin is associated with important clinical improvements without adverse effects on survival. Furthermore, these benefits have been seen in a wide range of patients, regardless of the cause of heart failure, the underlying rhythm, or concomitant medical therapy. The results of the DIG trial led the U.S. Food and Drug Administration to approve digoxin for the treatment of heart failure in 1997. According to revised ACC/AHA guidelines, the goals of digoxin therapy should be to alleviate symptoms and improve clinical status in patients with heart failure who are being treated with diuretics, an ACE inhibitor, or angiotensin receptor blocker, and a β-blocker. Digoxin has not been shown to be effective in patients with heart failure and preserved systolic function and may have adverse effects in patients with acute coronary syndromes. There are no data to support the use of digoxin in patients with asymptomatic left ventricular dysfunction.

Practical Considerations

Previous practice typically involved the use of full digitalizing doses to more rapidly achieve therapeutic levels. However, this is no longer recommended, and patients should simply be started on maintenance doses ranging from 0.0625 to 0.25 mg per day. Steady-state levels will be reached in approximately 1 week. Because drug elimination is primarily via the kidneys, digoxin doses must be adjusted in patients with acute or chronic kidney disease. There are a number of drug interactions that can significantly influence the efficacy and toxicity of digoxin.[103] Drugs known to increase digoxin levels include verapamil, spironolactone, and amiodarone. It is common practice to empirically reduce digoxin doses when initiating therapy with these drugs with close follow-up of digoxin levels. In addition, lower doses are recommended in elderly patients with heart failure.[112] Digoxin is not indicated to stabilize patients with acute decompensated heart failure (see Chapter 17) and should be used with caution in patients with post-myocardial infarction ischemia.

There is little evidence to support the routine use of serum digoxin levels to guide dose selection. However, it is reasonable to check a digoxin level during follow-up to identify patients who are receiving subtherapeutic doses, which in some cases is secondary to noncompliance. Digoxin levels are also extremely important in the evaluation of toxicity, such as in patients who develop nausea, anorexia, arrhythmias, atrioventricular block, or confusion. Digoxin toxicity is usually associated with serum levels of more than 2.0 ng/mL, but can occur with lower serum levels in the setting of hypokalemia or hypomagnesemia. Retrospective analyses from the DIG trial also suggest that serum digoxin concentrations in the "high-normal" range (e.g., 1.2 to 2.0 ng/mL) are associated with an increased risk of death for both men and women.[113,114] Taken together, these data suggest that the efficacy and safety of digoxin can be optimized by using doses that achieve a serum level in the range of 0.5 to 1.0 ng/mL. Of note, this recommendation has not yet been incorporated into reference ranges provided by clinical laboratories.

For many years, digoxin has been used to control the ventricular response rate in atrial fibrillation. In many situations, however, digoxin may not provide adequate rate control, especially during exercise, in patients with high sympathetic tone, or in the elderly. In patients with heart failure and atrial fibrillation already receiving a β-blocker, digoxin may be used as adjunctive therapy to control ventricular rate. Alternatively, amiodarone may be safely used for both ventricular rate control and restoration and maintenance of normal sinus rhythm.[115] In patients with symptomatic atrial fibrillation who do not respond to or who are intolerant of anti-arrhythmic therapy, options include atrioventricular junction ablation with back-up pacing or pulmonary vein isolation using radiofrequency or surgical ablation (see Chapters 20 and 24).

ALDOSTERONE ANTAGONISTS

Pathophysiology

In addition to systemic vasoconstriction and intravascular volume expansion, renal release of angiotensin in heart failure also results in increased levels of aldosterone, which is known to play an important role in the pathophysiology of heart failure.[116] Aldosterone promotes sodium retention, sympathetic activation, and baroreceptor dysfunction, and causes myocardial and vascular fibrosis. Although ACE inhibitors decrease aldosterone levels acutely, chronic ACE inhibition is associated with unsustained aldosterone suppression, referred to as "aldosterone escape."[117] Spironolactone competitively inhibits aldosterone-sensitive sodium channels in the cortical collecting tubule of the kidney and causes sodium and free-water excretion and potassium retention. Similar to the antiremodeling effects of ACE inhibitors and angiotensin receptor blockers, spironolactone inhibits aldosterone receptors in the heart and systemic vasculature that mediate pleiotropic effects leading to ventricular and vascular remodeling. In animal and human studies, spironolactone has been shown to prevent myocardial hypertrophy and fibrosis and to improve vascular compliance.

Clinical Efficacy

In the past, spironolactone was used infrequently as a potassium-retaining diuretic in patients with advanced heart failure, refractory edema, and hypokalemia. With the recognition of

"aldosterone" escape in heart failure and pilot studies demonstrating the safety of adding spironolactone to an ACE inhibitor,[118] a large mortality study of aldosterone antagonism was carried out. The Randomized Aldactone Evaluation Study (RALES) randomly assigned 1663 patients with severe heart failure and an ejection fraction of 35% or less to treatment with spironolactone (25 mg daily) or placebo.[119] The trial was stopped early after a mean follow-up of 24 months because of a 30% reduction in all-cause mortality rates with spironolactone. In addition, spironolactone improved symptoms and reduced the need for hospitalization owing to heart failure. In the Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS), the addition of aldosterone antagonists to optimal medical therapy reduced morbidity and mortality rates among patients with acute myocardial infarction complicated by left ventricular dysfunction and heart failure.[120] A multicenter randomized controlled trial is currently testing the effects of spironolactone on the morbidity and mortality rates in patients with heart failure and preserved systolic function.

Practical Considerations

Adjunctive therapy with aldosterone antagonists should be considered in selected patients with advanced heart failure or with post-myocardial infarction left ventricular dysfunction. The major risk associated with aldosterone blockade is hyperkalemia, which, in some cases, may be exacerbated by worsening renal function. Although the incidence of serious hyperkalemia was minimal in the RALES trial (1% placebo, 2% spironolactone; $P = 0.42$), it is important to note that patients were not enrolled if serum creatinine exceeded 2.5 mg/dL. In addition, potassium supplements were discontinued and electrolytes and renal function were monitored closely. After publication of these results, the rates of spironolactone prescriptions, hospitalization for hyperkalemia, and the associated mortality rate increased significantly.[121] Use of aldosterone antagonists in a broader patient population (e.g., the elderly, patients with chronic kidney disease, patients with heart failure with preserved ejection fraction)[122] and less rigorous monitoring of serum potassium levels[123] may explain these higher complication rates. Antiandrogenic effects, which may also limit the use of spironolactone, include painful gynecomastia, impotence, and menstrual irregularities (see Table 14–7). These hormonal effects are generally not seen with the selective aldosterone antagonist eplerenone.

Spironolactone should be initiated at a dose of 12.5 mg once daily and eplerenone at a dose of 25 mg per day. Potassium supplementation should be decreased or discontinued, and follow-up laboratory studies should be checked within 1 week. Patients should be counseled on avoiding foods (e.g., bananas, avocados, and broccoli) and salt substitutes that may contain high quantities of potassium. In addition, medications that can aggravate renal dysfunction, such as nonsteroidal anti-inflammatory drugs and cyclooxygenase-2 inhibitors, should be avoided. Any change in cardiac medications that may affect renal function or volume status, such as ACE inhibitor titration or use of combination diuretics, requires reassessment of serum electrolytes and renal function. Depending on the severity of hyperkalemia, treatment may include permanent discontinuation of the aldosterone antagonist, temporary discontinuation of other renin angiotensin system inhibitors and potassium supplements, and use of exchange resins.

HYDRALAZINE AND ISOSORBIDE DINITRATE

The combination of hydralazine and isosorbide dinitrate was shown in V-HeFT I to be an efficacious combination in terms of an improvement in survival compared with placebo.[40] Moreover, in V-HeFT II, this combination tended to increase exercise capacity and ejection fraction more than did enalapril.[41] Experience from these two large trials clearly demonstrated the usefulness and benefits of this drug combination. Retrospective analysis of the V-HeFT studies suggested particular efficacy in blacks.[124] To test whether this combination provides additional benefit in this specialized population, the African American Heart Failure Trial (A-HeFT) randomized 1050 self-identified blacks with NYHA functional class III-IV heart failure and dilated ventricles to receive a fixed dose of isosorbide dinitrate plus hydralazine (target daily doses of 120 mg and 225 mg, respectively) or placebo in addition to standard therapy.[125] The study was stopped early owing to a significantly higher mortality rate in the placebo group than in the group given isosorbide dinitrate plus hydralazine (10.2% versus 6.2%; P=0.02). Combination therapy also reduced the rate of heart failure hospitalizations by 33% and improved quality of life.

Although originally believed to be effective as vasodilators, emerging evidence suggests that the benefits of hydralazine and isosorbide dinitrate are related more to their biologic effects. For example, nitrates may attenuate myocardial and vascular remodeling by increasing the bioavailability of nitric oxide,[126] and hydralazine has been shown to prevent nitrate tolerance through antioxidant activity.[127] Hydralazine attenuates nitrate tolerance through inhibition of NADH/NADPH oxidases as well as through direct scavenging of reactive oxygen species (see Chapter 5). By favorably altering the nitroso-redox balance in heart failure,[126] the combination of nitrates and hydralazine may prevent myocardial hypertrophy, fibrosis, and apoptosis and may improve vascular compliance. Although these mechanisms have not been explored directly in randomized controlled trials, preliminary data from the A-HeFT study demonstrates clinical benefits independent of baseline blood pressure as well as reverse ventricular remodeling. It is also not known whether these mechanisms of benefit are of greater importance for blacks than for other racial or ethnic groups. Preliminary studies demonstrate impaired flow-mediated vasodilation in black hypertensive patients compared with whites but are limited by small numbers and potential confounders.[128] Others have shown a more generalized abnormality in endothelium-dependent vasodilation in heart failure,[129] which could be favorably affected by nitric oxide-enhancing therapy. Additional studies to understand the genetic and environmental determinants of the effect of hydralazine and nitrates on disease progression in heart failure are currently underway.

Practical Considerations

A number of factors have limited the widespread application of hydralazine-isosorbide dinitrate to patients with heart

failure. First, in V-HeFT II, the ACE inhibitor enalapril resulted in a significant improvement in survival compared with hydralazine and isosorbide dinitrate. Second, this combination is considerably more cumbersome for patient compliance because the target doses used in the V-HeFT studies were 160 mg of isosorbide dinitrate (40 mg four times daily) and 300 mg of hydralazine (75 mg four times daily). Although a fixed combination pill that can be taken three times daily is now available, compliance and cost remain problematic for patients already taking several heart failure medications. Third, this combination has a number of side effects, including headaches and flushing associated with nitrate preparations and gastrointestinal symptoms from hydralazine. In the V-HeFT trials, between 18% and 38% of patients discontinued one or both of the medications owing to side effects. In A-HeFT, adverse effects of isosorbide dinitrate-hydralazine included headache (50%), dizziness (32%), and nausea (10%) with one in five patients discontinuing the fixed-dose combination.

In clinical practice, the combination of hydralazine and isosorbide dinitrate may be particularly useful in patients who have persistent symptoms of heart failure, but are unable to tolerate renin-angiotensin system inhibitors. However, there have been no studies specifically targeting this patient population, and hydralazine and nitrates should not be substituted for ACE inhibitors or angiotensin receptor blockers. Many physicians use nitrates in their patients with heart failure, especially those with underlying ischemic heart disease.[130] Based on both mechanistic and trial data, it would be prudent to administer nitrates in combination with hydralazine. Furthermore, revised ACC/AHA guidelines recommend the addition of a combination of hydralazine and a nitrate for patients with reduced ejection fraction who are already taking an ACE inhibitor and β-blocker and who have persistent symptoms.

The most important recommendation regarding this regimen is to initiate therapy with low doses followed by gradual dose titration over several weeks. Initial doses of more than 10 mg isosorbide dinitrate and 25 mg hydralazine may produce headaches, but gradual upward titration is usually well tolerated. Prophylactic acetaminophen can reduce the problems associated with nitrate-induced headache, whereas nonsteroidal anti-inflammatory agents should be avoided. Several long-acting nitrate preparations are available, but the clinical experience with these formulations in patients with heart failure is limited.

CALCIUM CHANNEL BLOCKERS

Calcium channel blocking agents have been considered for use in patients with heart failure because these drugs have potent vasodilator actions and may reduce ischemia in patients with left ventricular dysfunction due to coronary artery disease.[131] Hemodynamic studies have demonstrated that acute administration of calcium channel blockers is associated with a reduction in systemic vascular resistance and an increase in cardiac output. However, the acute hemodynamic effects of nifedipine, verapamil, and diltiazem have not been uniform, and short- and long-term treatment with these agents has been associated with serious adverse events and excess mortality, possibly related to negative inotropic effects or neurohormonal stimulation.

Second-generation calcium channel blockers with greater selectivity for vascular actions have also been evaluated in heart failure. Amlodipine, a long-acting dihydropyridine with potent vasodilator effects, is approved for the treatment of hypertension and angina. In the Prospective Randomized Amlodipine Survival Evaluation (PRAISE) study, 1153 patients with severe heart failure and an ejection fraction of less than 30% were randomized to amlodipine (up to 10 mg daily) or placebo for 6 to 33 months.[132] Amlodipine had no effect on the primary combined endpoint of death or major cardiovascular hospitalization, but tended to reduce all-cause mortality (risk reduction, 16%; $P = 0.07$), particularly in nonischemic cardiomyopathy. However, PRAISE II demonstrated no beneficial effects of amlodipine on neurohormonal stimulation or survival in this population.[133] Similar negative findings were seen in the V-HeFT III study in which long-term therapy with felodipine had no beneficial effects on exercise tolerance, hospitalizations, or survival, and was associated with a higher incidence of peripheral edema.[134] Finally, data from the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) suggest that the antihypertensive benefits of amlodipine may be offset by an increased risk of developing heart failure.[135]

Based on these cumulative data, it is recommended that most calcium channel blockers should be avoided in patients with heart failure. The primary benefit may be mainly from control of hypertension or reduction of ischemia, although alternative agents (e.g., nitrates) or treatments (e.g., revascularization) are preferred. Of the available calcium channel blockers, only the vasoselective agents have not been shown to adversely affect survival in patients with heart failure and reduced ejection fraction. Calcium channel blockers may have a role in controlling heart rate or improving symptoms in patients with heart failure and preserved ejection fraction (see later).

POSITIVE INOTROPIC AGENTS

Oral Positive Inotropes

The search for safe and effective inotropic agents for patients with heart failure was based on the observation that the clinical syndrome of heart failure results from a primary defect in myocardial contractility and that many patients have symptoms that are refractory to standard therapy. During the 1980s and early 1990s, there was an extraordinary effort to develop an orally administered inotropic agent.[136] The majority of studies focused on phosphodiesterase (PDE) inhibitors, which produce a marked hemodynamic benefit when administered acutely to patients with decompensated heart failure. However, enthusiasm for this class of drugs decreased significantly when multicenter trials failed to detect a significant improvement in symptoms and exercise tolerance[137] and when the PROMISE (Prospective Randomized Milrinone Survival Evaluation) trial demonstrated increased mortality rates in patients treated with milrinone.[138] Other oral inotropes with PDE inhibitor effects have also been associated with excess mortality in heart failure, including vesnarinone[139] and high-dose enoximone.[140] Studies of low-dose enoximone have yielded disappointing clinical results (although neutral effects on mortality) in patients with advanced heart failure.[141]

Intravenous Positive Inotropes

An additional treatment that can be considered in patients with refractory heart failure is intravenous dobutamine or milrinone.[142] Dobutamine augments cardiac contractility primarily via stimulation of β-adrenergic receptors and is a modest vasodilator, whereas milrinone exerts potent inotropic and direct vasodilator effects via PDE inhibition in the myocardium and vasculature (see Chapter 17 for discussion of pharmacology and short-term use of inotropic therapy in acute decompensated heart failure). A small number of patients with end-stage heart failure cannot be weaned from acute inotropic therapy. Evidence of failure to wean includes the development of symptomatic hypotension, recurrent congestion, and/or worsening renal function. In practice, more than one attempt should be made to wean inotropes, and weaning should not be undertaken until the patient has achieved clinical stability. In addition, ACE inhibitors and β-blockers may need to be held for increased blood pressure and renal perfusion. Invasive monitoring for "optimization" of hemodynamics is not required or recommended.[143] For selected patients deemed to be inotrope dependent, chronic intravenous therapy may be used as a bridge to transplant or to the end of life.

Bridge to Transplant

Because of the limited donor supply, the majority of patients receiving heart transplants require pharmacologic or mechanical cardiac support as a bridge to transplant (see Chapter 18). Options for inotrope-dependent patients include in-hospital or continuous home intravenous therapy. Criteria for discharge to home include hemodynamic stability on low-dose of a single agent, improved functional status, and family and nursing support. Implantable cardioverter-defibrillators (ICDs) are recommended to prevent sudden death. Home dobutamine and milrinone have been used successfully to bridge patients to transplant, although readmissions and complications are common. In one study, 59% of patients required readmission: two thirds of readmissions due to worsening heart failure and one third due to infection or occlusion of the indwelling catheter.[144]

Bridge to End of Life

For patients with refractory heart failure who are not transplant candidates, chronic inotropic therapy may be used to palliate symptoms at the end of life. This practice has become more common as cardiologists care for older patients who have exhausted medical and surgical options, and for whom the use of β-blockers and ICDs has decreased the risk of sudden death in favor of progressive pump failure. Hershberger and colleagues[142] reported a 10-year experience with home inotropic infusions in nontransplant patients with end-stage heart failure. Although patients were ambulatory and pain free at the time of discharge, the median survival was only 3 months, and one-third of patients died in the hospital. In practice, palliative inotropic therapy requires collaboration with home hospice to facilitate coadministration of narcotics and anxiolytics and requires a discussion with the patient and family about turning off ICDs.

Inotropic agents have also been administered intermittently at home or in an infusion clinic. Although initial uncontrolled studies suggested improvement in symptoms and decreased hospitalizations, small randomized studies have demonstrated either no benefit or excess mortality.[145] The primary mechanism responsible for increased mortality associated with chronic inotropic infusions is believed to be an increase in intracellular cyclic AMP, which exerts a direct toxic effect on the myocardium leading to further contractile dysfunction and proarrhythmia.[146] Hypersensitivity myocarditis with dobutamine may also contribute to hemodynamic deterioration.[147] Because of the lack of data demonstrating efficacy and the concerns about toxicity, the use of intermittent inotropic infusions is not recommended for the treatment of advanced heart failure.[4]

ANTITHROMBOTIC THERAPY

Many clinicians have recommended anticoagulation for prophylaxis against thromboembolism and stroke for patients with dilated cardiomyopathy in the absence of specific contraindications.[148] This recommendation is based on the presence of ventricular thrombus in as many as 75% of cases of dilated cardiomyopathy[149] and on the repeated observation of a high incidence of embolic events in this patient population.[150,151] In addition, retrospective analyses have suggested that the incidence of embolic events[152] and all-cause mortality[153] is reduced in patients who are treated with anticoagulants. The mechanisms underlying the increased risk of thromboembolism in patients with heart failure include stasis of blood in the cardiac chambers and systemic venous circulation and hypercoagulability. Additionally, patients with heart failure are at increased risk for the development of atrial fibrillation,[154] which predisposes to cardiac thrombi formation.

Recommendations for the routine use of anticoagulants in patients with heart failure have been reconsidered in view of data from multicenter trials. In V-HeFT II, there were only 46 embolic events in 804 patients followed for an average of 2.5 years.[155] Furthermore, V-HeFT II demonstrated an *increased* thromboembolic rate in patients receiving anticoagulation compared with those not receiving anticoagulation (4.9 versus 2.1 per 100 patient years, $P = 0.01$). In SOLVD, the annual incidence of thromboembolic events was only 2.4% in women and 1.8% in men. The use of anticoagulants, as directed by individual physicians, was not associated with a reduced incidence of thromboembolism.[156] Unfortunately, randomized controlled trials of anticoagulation in heart failure have been inconclusive owing to small sample size[69] or have been prematurely stopped owing to lack of enrollment.[68]

Because the risk of thromboembolism and the benefits of anticoagulants may not be as large as once considered, and in the absence of data from controlled trials,[157] recommendations for anticoagulation for patients with heart failure should be made on an individual basis. Indications for anticoagulation are atrial fibrillation and a history of thromboembolism. Consideration of anticoagulation should also be given to patients with intracavitary thrombus or spontaneous contrast demonstrated by echocardiography, or with specific diagnoses associated with a higher thromboembolic risk such as cardiac amyloidosis, left ventricular noncompaction, and peripartum cardiomyopathy. Younger patients with familial dilated cardiomyopathy and a family history of thromboembolism should also be considered for anticoagulation. In patients with

contraindications to warfarin, an alternate regimen is to use a single daily dose of aspirin, but there are no controlled data to support this recommendation. In addition, as discussed, aspirin may attenuate the benefits of ACE inhibition in heart failure and is not recommended for patients with nonischemic cardiomyopathy.

ANTIARRHYTHMIC THERAPY

The indications for and the efficacy of antiarrhythmic agents in the management of heart failure remain subjects of great controversy.[158] The original rationale for considering these agents as adjunctive therapy was based on the observation that as many as 30% to 50% of all deaths in patients with heart failure can be classified as sudden death. Frequent ventricular premature contractions and nonsustained ventricular tachycardia on Holter recordings are almost universal in patients with heart failure and are frequent sources of concern in hospitalized patients who are on telemetry monitoring. These arrhythmias are likely related to a number of factors, including fibrosis, wall stress, left ventricular dilatation, electrolyte imbalances, high levels of circulating catecholamines, and proarrhythmic effects of drugs such as digoxin. All of these factors suggested that antiarrhythmic therapy and suppression of high-risk arrhythmias might be beneficial in this patient population. However, the understanding that sudden death in heart failure may be caused by ischemia or bradyarrhythmias,[159] and the increased recognition of adverse events associated with antiarrhythmic therapy including proarrhythmia, worsening heart failure,[160] and excess mortality rate as shown in controlled trials[161] led to the recommendation to avoid the use of class I antiarrhythmic drugs.

Subsequent studies focused on the role of class III agents (e.g., amiodarone, d-sotalol, and dofetilide) in heart failure. Amiodarone may substantially reduce the frequency and complexity of asymptomatic ventricular arrhythmias, and initial studies suggested that amiodarone may have a beneficial impact on morbidity and mortality rates in patients with heart failure.[162] The Congestive Heart Failure-Survival Trial of Antiarrhythmic Therapy (CHF-STAT) was a prospective, double-blind study in which 674 patients with heart failure, an ejection fraction of 40% or less, and asymptomatic ventricular ectopy were randomized to amiodarone or placebo for a median of 45 months.[163] As expected, amiodarone decreased ventricular ectopy compared with placebo. In contrast to a smaller, unblinded study, CHF-STAT demonstrated no beneficial effect of amiodarone on mortality. The Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) also showed no effect of amiodarone on survival in a study of more than 2500 patients with ischemic and nonischemic cardiomyopathy.[164]

Although amiodarone has no role in the treatment of heart failure per se, it may be useful in the management of symptomatic ventricular or atrial arrhythmias that complicate heart failure. In particular, amiodarone may be administered acutely to control ventricular response in heart failure patients with atrial fibrillation, and its long-term use may restore and maintain sinus rhythm.[115,165] Amiodarone may also be used to suppress symptomatic ventricular tachycardia, especially in patients who are receiving frequent ICD shocks. Close monitoring for adverse reactions, including hepatic, pulmonary and thyroid toxicity, and knowledge of drug interactions such as increased digoxin levels and elevated INR are critical to the safe use of amiodarone. In contrast to type I agents, amiodarone appears to be associated with a very low risk of proarrhythmia in patients with left ventricular dysfunction.[166]

Other class III antiarrhythmic agents that have been tested in heart failure are the potassium-channel blocker, d-sotalol, and dofetilide. In the Survival With Oral d-sotalol (SWORD) trial, 3121 patients with ischemic cardiomyopathy were randomized to treatment with d-sotalol (200 mg twice daily) or placebo.[167] The trial was stopped early because of the excess mortality rate in the d-sotalol group, which appeared to be primarily arrhythmic. The Danish Investigations of Arrhythmia and Mortality on Dofetilide (DIAMOND) study group demonstrated no effect of dofetilide on the mortality rate in 1518 patients with symptomatic left ventricular dysfunction.[168] Like amiodarone, dofetilide was effective in converting atrial fibrillation to sinus rhythm; however, it was associated with a 3.3% incidence of torsades de pointes. The role of ICDs for primary and secondary prevention of sudden death in heart failure is discussed in Chapter 15.

SPECIAL CONSIDERATIONS

The majority of ambulatory patients with heart failure and reduced ejection fraction can be treated with medications according to the recommendations presented in this chapter. There are, however, several subgroups of patients who merit special consideration because other pharmacologic therapy may provide important clinical benefit.

Patients with Heart Failure and Normal Ejection Fraction

As many as one half of patients presenting with heart failure have a normal or near normal left ventricular ejection fraction.[169] Heart failure with preserved systolic function is relatively uncommon in young or middle-aged adults, yet the prevalence can exceed 50% in older patients, especially elderly women with hypertension.[170] In addition to hypertensive heart disease, other causes of heart failure with normal ejection fraction are restrictive, hypertrophic and infiltrative cardiomyopathies, and constrictive pericarditis. Diastolic dysfunction is believed to be the primary mechanism responsible for this clinical syndrome, but other pathophysiologic factors may contribute to disease progression, including arterial stiffness, sodium avidity, and renal dysfunction. Some data suggest that long-term survival is similar among patients with reduced versus preserved systolic function,[171] but most studies show that heart failure with normal ejection fraction is associated with a lower risk of death (Table 14–10).[172]

Large randomized trials have confirmed survival and other benefits of ACE inhibitors and β-blockers in patients with heart failure and reduced ejection fraction, yet there have been few such trials in patients with preserved systolic function. As a result, therapy is based primarily on the results of clinical investigations in small groups of patients, and on pathophysiological concepts.[173] Principles of therapy include blood pressure and heart rate control, reduction in cardiac filling pressures, and prevention of myocardial ischemia (Table

Table 14–10 Mortality in Heart Failure with Reduced versus Preserved Ejection Fraction

Study	Patients, *N*	Follow-Up	Mortality with Reduced EF	Mortality with Preserved EF	RR of Death with Preserved EF
Cohn 1990[224]	623	2.3 years	19% per year	8% per year	0.42
Ghali 1992[225]	78	2 years	46%	26%	0.56

Table 14–11 ACC/AHA Recommendations for Management of Heart Failure with Preserved Ejection Fraction

Class	Recommendation	Level of Evidence
I	Control systolic and diastolic hypertension	A
	Control ventricular rate in atrial fibrillation	C
	Diuretics to control pulmonary congestion and peripheral edema	C
IIa	Coronary revascularization if ischemia is having an adverse effect on cardiac function	C
IIb	Restoration of sinus rhythm if atrial fibrillation is present	C
	β-Blockers, ACE inhibitors, ARBs, or calcium channel blockers to minimize symptoms of heart failure	C
	Digoxin to minimize symptoms of heart failure	C

ACC, American College of Cardiology; AHA, American Heart Association; ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker. Adapted from Hunt SA, Abraham WT, Chin MH, et al: ACC/AHA 2005 guideline update for the diagnosis and management of chronic heart failure in the adult: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Update the 2001 Guidelines for the Evaluation and Management of Heart Failure): Developed in collaboration with the American College of Chest Physicians and the International Society for Heart and Lung Transplantation: Endorsed by the Heart Rhythm Society. Circulation 2005;112:e154-e235.

14–11). In heart failure due to hypertension, blood pressure control is important to prevent progression of left ventricular hypertrophy and possibly to promote its regression. In addition, effective antihypertensive therapy may improve diastolic filling properties, relieve the load on the left atrium, and help preserve sinus rhythm.

Calcium channel blockers may reduce symptoms of diastolic heart failure not only by lowering blood pressure, but also by improving ventricular relaxation.[174] Renin-angiotensin system inhibitors (e.g., ACE inhibitors and angiotensin receptor blockers) may also improve ventricular relaxation, slow or reverse myocardial fibrosis, and prevent atrial fibrillation.[175] There is, however, no evidence that either calcium channel blockers or ACE inhibitors improve survival in patients with heart failure and normal ejection fraction. The effect of angiotensin receptor blockers on morbidity and mortality rates was tested in the CHARM-Preserved study. In CHARM-Preserved, 3023 patients with NYHA functional class II-IV heart failure and an ejection fraction greater than 40% were randomized to receive candesartan (target dose 32 mg once daily) or placebo and followed for a median of 36 months.[217] Candesartan had no significant effect on the primary combined endpoint of cardiovascular death or heart failure hospitalization (hazard ratio 0.89; 95% CI, 0.77 to 1.03; $P = 0.12$), but it did reduce the number of patients admitted once or multiple times for heart failure and decreased the risk of diabetes. Adverse events, including hypotension, renal insufficiency, and hyperkalemia, were more common with candesartan. Ongoing multicenter studies will help to further define the risk-benefit profile of renin-angiotensin-aldosterone system inhibitors in patients with heart failure and preserved systolic function (Table 14–12).

Patients with left ventricular hypertrophy are prone to subendocardial ischemia, even in the absence of ischemic heart disease. Ischemia increases myocardial diastolic stiffness and exacerbates diastolic dysfunction. Because most coronary flow occurs in diastole, tachycardia with reduced diastolic filling time compromises subendocardial perfusion. Heart rate control is therefore central to preventing or treating ischemia associated with heart failure and preserved systolic function. β-Blockers and some calcium channel blockers (e.g., verapamil) are useful negative chronotropic agents. For patients with ischemic heart disease, percutaneous or surgical revascularization may be indicated to treat ischemia.

Pulmonary venous congestion associated with diastolic dysfunction usually responds rapidly to preload reduction with diuretics and/or nitrates. Because of increased myocardial stiffness, however, a small decreases in left ventricular volume can cause marked decreases in left atrial filling pressure, stroke volume, and cardiac output. It is, therefore, important to avoid excessive preload reduction, which can cause symptomatic hypotension, especially in the elderly. Diuretic therapy should be initiated with a small dose of a loop diuretic (e.g., furosemide 20 mg, bumetanide 0.5 mg). If effective diuresis is not achieved, the dose should be increased or a second diuretic agent (e.g., metolazone 2.5 to 5 mg) may be added.

Table 14–12 Morbidity and Mortality Trials in Heart Failure with Preserved Systolic Function

Study	N	Agent	Entry Criteria	Primary Endpoint	Expected Completion
I-PRESERVE[231]	4128	Irbesartan vs. placebo	Age ≥ 60 LVEF ≥ 45%	All-cause death or CV hospitalization	2007
PEP-CHF[232]	1000	Perindopril vs. placebo	Age ≥ 70 LVEF ≥ 40%	All-cause death or HF hospitalization	NA
TOPCAT[233]	4500	Spironolactone vs. placebo	Age ≥ 50 LVEF ≥ 45%	CV death or HF hospitalization	2011

CV, cardiovascular; HF, heart failure; I-PRESERVE, Irbesartan in Heart Failure with Preserved Systolic Function; LVEF, left ventricular ejection fraction; NA, not available; PEP-CHF, Perindopril for Elderly Patients with Chronic Heart Failure; TOPCAT, Trial of Aldosterone Antagonist Therapy in Adults With Preserved Ejection Fraction Congestive Heart Failure.

Because of increased left ventricular diastolic stiffness, some patients with heart failure and normal ejection fraction have reduced passive ventricular filling in early and mid-diastole and depend on an active atrial contribution to late ventricular filling. Thus, there has been a strong rationale for maintaining sinus rhythm to achieve adequate stroke volume and cardiac output. Trials that have tested rate versus rhythm control strategies in atrial fibrillation have failed to demonstrate benefits of rhythm control and show higher rates of hospitalization and adverse drug effects.[176] Unfortunately, these trials have included few patients with heart failure. Until data from ongoing clinical trials are available, β-blockers, calcium channel blockers, or digoxin may be used alone or in combination to control the ventricular response. If rate control is ineffective, treatment options are chemical or electrical cardioversion, catheter ablation of atrial fibrillation (i.e., pulmonary vein isolation), or ablation of the atrioventicular junction with pacemaker implantation.[177] All patients with persistent or paroxysmal atrial fibrillation should receive anticoagulation therapy unless there is a contraindication to warfarin.

In general, positive inotropic agents should not be used in patients with heart failure and preserved systolic function because these agents may adversely affect myocardial energetics, induce ischemia, and promote tachyarrhythmias. In the DIG ancillary study, the addition of digoxin to patients with heart failure and an ejection fraction greater than 45% tended to reduce the combined endpoint of death or hospitalization due to worsening heart failure (risk ratio, 0.82; 95% CI, 0.63 to 1.07) but had no effect on all-cause mortality.[108]

Patients with Ischemic Heart Disease

There are several ways in which ischemic heart disease can complicate the management of heart failure. Symptoms of angina pectoris and myocardial ischemia are often difficult to distinguish from the exertional dyspnea and fatigue associated with heart failure. However, patients who have myocardial ischemia frequently require additional anti-ischemic therapy to maximize clinical status. Therefore, in addition to standard treatment with renin-angiotensin system inhibitors, β-blockers, and diuretics, these patients may improve further with the addition of nitrates. Ranolazine, an inhibitor of the slow inactivating sodium current (I_{Na}), has also been approved for the treatment of chronic angina (see Appendix 1).[178] The safety and efficacy of ranolazine have not been tested in heart failure, but there is theoretical reason to believe that late I_{Na} inhibition could improve myocardial efficiency and lead to functional benefits,[179] although this remains unproven.

Other patients with ischemic heart disease may have periodic decompensations that are triggered by episodes of myocardial ischemia. In addition to anti-ischemic pharmacotherapy, these patients may benefit from coronary revascularization, with either coronary artery bypass graft surgery or percutaneous coronary intervention. An important therapeutic consideration in these patients is the presence of hibernating myocardium.[180] Many patients will experience marked improvement in left ventricular function following bypass surgery, and assessment of myocardial viability appears to be an important tool in predicting which patients will have a favorable response.[181] The role of surgical revascularization with or without ventricular reconstruction in patients with ischemic cardiomyopathy is discussed in Chapter 16. For patients with ischemia not amenable to direct revascularization, enhanced external counterpulsation (EECP) may reduce angina and improve exercise tolerance and quality of life; however, the mechanisms responsible for the therapeutic response and the impact on long-term morbidity and mortality rates remain unknown.[182] For selected patients with end-stage ischemic cardiomyopathy, heart transplantation may be the preferred option (see Chapter 18).

Patients with Valvular Heart Disease

Patients with significant regurgitant valvular heart disease represent another difficult patient subgroup. Many patients with significant left ventricular dilatation will have functional mitral regurgitation due to annular dilatation. Other patients will have concomitant pathology of the mitral apparatus due to a history of rheumatic heart disease, myxomatous degeneration, or ischemic heart disease and papillary muscle dysfunction. Frequently, the use of vasodilator and diuretic therapy will adequately reduce the regurgitant volume resulting in hemodynamic and symptomatic improvement, which may be long lasting.[183] In other cases, in which abnormalities of the mitral valve or subvalvular apparatus make a primary contribution to symptoms and left ventricular dysfunction, valve repair or replacement may have important therapeutic benefit. However, there is no reliable method to distinguish consistently those patients who will benefit from mitral valve surgery from those who experience a progressive decline in ventricular function after mitral surgery. Mitral valvuloplasty

has also been performed safely in patients with dilated cardiomyopathy and severe mitral regurgitation due to annular dilatation with encouraging results in uncontrolled studies.[184] However, the long-term benefits of mitral valve repair compared with medical therapy in this subset of patients remain unproved.[101] Novel devices for percutaneous mitral valve repair are under development.[185]

Patients with Diabetes

Overall, diabetes is present in 20% to 30% of patients with heart failure, and there are several concerns about pharmacologic treatment of diabetes in heart failure patients. The thiazolidinedione (TZD) class of oral hypoglycemic agents has gained widespread popularity for the treatment of insulin resistance owing to several advantageous ancillary effects on lipid metabolism, vascular endothelial function, and inflammatory cytokines.[186] However, these agents may increase fluid retention and exacerbate heart failure symptoms. In general, TZDs produce a 6% to 7% increase in circulating intravascular volume and a 2- to 4-kg weight gain. In a study of diabetic patients with heart failure, initiation of TZDs was associated with a 17% increase in fluid retention as defined by a 10-pound involuntary weight gain.[187] Risk factors include older age, hypertension, and ischemic heart disease. TZD-induced fluid retention is dose-related and exacerbated by concomitant insulin use. Peripheral rather than central edema predominates and usually resolves on drug withdrawal. These agents are contraindicated in patients with NYHA functional class III-IV heart failure and should be used with caution in mild heart failure.

Metformin is another popular oral insulin sensitizer. According to the package insert, metformin is contraindicated in patients with “heart failure requiring pharmacological therapy” because of the risk of lactic acidosis.[188] Although the overall incidence of life-threatening lactic acidosis is low, the U.S. Food and Drug Administration assigned a black box warning in response to post-marketing reports of increased risk among patients with chronic hypoperfusion and hypoxia. Despite cautionary alerts, a review of prescribing patterns among Medicare beneficiaries hospitalized with heart failure reported that nearly one fourth of patients were discharged on either a TZD or metformin.[188] Given the increased awareness of the beneficial cardiovascular effects of these agents when used in the general population, further data are needed to examine their risk-benefit ratio in patients with heart failure.

Gender, Race, and Ethnic Considerations

With few exceptions, blacks and some other racial minorities and women have been underrepresented in randomized controlled trials of new treatments for heart failure. However, most subgroup and meta-analyses have shown consistent benefits of standard therapy across a broad range of patient populations.[66] ACE inhibitors, angiotensin receptor blockers, β-blockers, and spironolactone are equally effective in men and women with symptomatic left ventricular dysfunction, whereas data on digoxin have been conflicting. In a post-hoc subgroup analysis of the DIG trial, Rathore and associates[189] found that women who were randomized to digoxin had a higher mortality rate compared with women who received placebo (33.1% versus 28.9%), an effect that was not seen in men. Additional analyses, however, suggested that this gender-treatment interaction may have been attributed to higher serum digoxin concentrations in women.[113] Other treatment recommendations specific to women with heart failure include avoiding ACE inhibitors, angiotensin receptor blockers and Coumadin (warfarin) during pregnancy, and exercising caution in the use of cardiotoxic chemotherapy (e.g., trastuzumab) in the treatment of breast cancer. For men with heart failure and erectile dysfunction, intermittent use of PDE type 5 inhibitors (e.g., sildenafil, vardenafil) appears safe and effective.[190]

Compared with whites, blacks appear to develop heart failure at an earlier age and to have more rapid progression of symptoms.[191] The increased awareness of these differences in heart failure epidemiology has led to a greater emphasis by heart failure specialists in defining the most effective therapy in blacks. Although retrospective analyses suggest that blacks with hypertension or heart failure experience less efficacy with ACE inhibitors, a current meta-analysis demonstrated similar mortality reduction in blacks and nonblacks with heart failure.[66] The data from randomized controlled trials of β-blockers are less clear with carvedilol showing equal efficacy in black and nonblack patients,[80] whereas bucindolol tended to increase morbidity and mortality rates in blacks.[91] Excluding results from the BEST trial, Shekelle and colleagues[66] analyzed race-stratified data on β-blockers from the COPERNICUS, MERIT-HF, and U.S. Carvedilol studies and found that the relative risk on the effect of mortality for black patients was 0.67 (95% CI, 0.38 to 1.16). As discussed earlier, the combination of hydralazine and isosorbide dinitrate reduces morbidity and mortality rates in self-identified blacks with symptomatic left ventricular systolic dysfunction, and is now recommended as part of standard therapy in addition to ACE inhibitors and β-blockers.[192]

Like Blacks, Hispanics and other ethnic minorities have received little attention in heart failure trials. In the absence of data showing lack of efficacy or excess toxicity, renin-angiotensin-aldosterone system inhibitors, β-blockers, and other pharmacologic agents used to treat heart failure should be prescribed according to indications outlined in this chapter and national guidelines.[4,192]

Patients with Myocarditis

The underlying causes, pathophysiology, clinical manifestations, and diagnostic evaluation of myocarditis are discussed in detail in Chapter 60 in HD7e and other reviews.[193] In brief, myocarditis is a rare disease for which pathophysiologic mechanisms are not well understood, and for which there is no diagnostic “standard” or proven therapy. Primary myocarditis is believed to be the result of viral and post-viral immunologic effects on the heart,[193] and most therapies have been aimed at modulating the immune response. For patients with secondary myocarditis, inflammation of the myocardium due to a known agent (e.g., *Aspergillus*, mycobacterium tuberculosis) frequently resolves with treatment of the causative agent.

Most patients with myocarditis have a history of an acute viral illness, although there is usually a delay between the initial viral symptoms and the onset of symptoms of heart muscle disease. This delay is probably dependent on the viral etiology and host response. Adults with fulminant myocarditis display the least delay and present with severe heart failure.[194] Rarely, patients may present with embolic phenomena, such

as myocardial infarction or sudden death. Although acute and convalescent viral titers may be of some value in determining the most likely cause of myocarditis, these tests suggest only an association and do not establish the diagnosis. Furthermore, noninvasive nuclear imaging studies with gallium or antimyosin antibody have relatively high false-negative rates and are too nonspecific to be of diagnostic use.[195] The diagnosis of myocarditis can be established by endomyocardial biopsy and requires evidence of myocyte damage associated with an inflammatory cell infiltrate not typical of damage caused by ischemic heart disease. Because of sampling error, the false-negative rate of endomyocardial biopsy to diagnose myocarditis may be as high as 30% when up to five specimens are obtained.[196]

Currently, there are no clinically available antiviral agents for treating the enteroviruses (coxsackieviruses B and A, echovirus, and adenovirus) that cause most cases of primary myocarditis. In addition, immunization to prevent myocarditis is impossible because of the large number of potential causative agents. Because most cases of myocarditis are believed to be immune-mediated, immunosuppressive agents have received the most attention in the search for effective therapy. However, the results of controlled trials have been disappointing.[197-199]

The rate and degree of improvement in ventricular performance that have been observed in uncontrolled trials of immunosuppressive therapy have raised the possibility that many patients with myocarditis recover spontaneously. The Myocarditis Treatment Trial was a prospective, randomized National Institutes of Health-supported study that sought to determine the effect of immunosuppressive therapy on left ventricular function in patients with myocarditis.[198] More than 2200 patients who presented with heart failure of less than 2 years' duration and an ejection fraction of less than 45% underwent endomyocardial biopsy. Two hundred patients (≈10%) had biopsy-proven myocarditis, and of these, only 111 were randomized to receive conventional therapy alone or combined with prednisone and either cyclosporine or azathioprine. After 28 weeks of therapy, the mean left ventricular ejection fraction increased from 25% to 34% in the group as a whole but did not differ significantly between the groups. In addition, there was no difference in survival with overall 1- and 4-year mortality rates of 20% and 56%, respectively. Another immunomodulatory therapy that has been proposed for the treatment of myocarditis based on preclinical and uncontrolled clinical studies is intravenous immune globulin (IVIG).[200] However, a randomized controlled trial of IVIG (2 gm/kg) in 62 patients with new onset heart failure and an ejection fraction of 40% or less failed to show a benefit over placebo.[199] The mean ejection fraction increased dramatically in the group as a whole (from 25% to 42%), and prognosis was excellent with a 2-year event-free survival of 88%.

Based on these results, many referral centers have become less aggressive in performing endomyocardial biopsy to diagnose myocarditis given the lack of proven therapy.[201] In addition, there are data showing no difference in survival between patients with myocarditis and those with idiopathic dilated cardiomyopathy.[202] However, in the subgroup of patients who present with hemodynamic compromise, endomyocardial biopsy to confirm a diagnosis of fulminant myocarditis versus giant cell or hypersensitivity myocarditis can have important prognostic and therapeutic implications. Adults with fulminant lymphocytic myocarditis respond poorly to immunosuppressive therapy but may benefit from aggressive hemodynamic support, including mechanical cardiac assist, as a "bridge" to recovery.[194] By contrast, patients with giant cell myocarditis have a poor prognosis and should be urgently evaluated for mechanical assist and transplant.[203] New understanding of disease mechanisms will hopefully lead to improved diagnostic and therapeutic strategies for myocarditis.[204]

FUTURE DIRECTIONS IN PHARMACOLOGIC THERAPY

Future directions for heart failure therapy include novel neurohormonal antagonists, modulation of myocardial energetics, and treatment of comorbidities such as anemia and pulmonary hypertension (see Table 14–9). Plasma levels of arginine vasopressin are elevated in patients with heart failure and may contribute to disease progression through stimulation of V_{1a} and V_2 receptors, causing vasoconstriction and free-water retention, respectively.[205] Short-term administration of vasopressin receptor antagonists in patients with decompensated heart failure improves hemodynamics and increases urine output without adversely effecting electrolytes or renal function.[206,207] The effect of chronic vasopressin receptor blockade on clinical outcomes is currently being tested in controlled clinical trials.[208] Like vasopressin, adenosine may contribute to maladaptive volume regulation in patients with coexistent cardiac and renal failure. Adenosine mediates intrarenal vasoconstriction and inhibition of tubuloglomerular feedback via stimulation of A_1 receptors.[209] In pilot studies, selective A_1 receptor antagonists show modest diuretic effects but offer the potential to attenuate diuretic-induced worsening of renal function.[210] Controlled trials are currently underway to determine the safety and efficacy of these agents in patients with advanced heart failure.

Another novel neurohormonal approach to managing patients with chronic decompensated heart failure is intermittent outpatient infusions of natriuretic peptides.[211] Although these compounds cause modest diuresis and natriuresis, improve hemodynamics, and inhibit neurohormonal activation acutely, their long-term effects on ventricular remodeling and disease progression remain unproven. Finally, modulation of myocardial energetics is also emerging as a novel therapeutic target in cardiovascular disease.[179] Anti-anginal agents such as trimetazidine and ranolazine may increase cardiac performance in heart failure without dependence on changes in oxygen consumption or improvement in hemodynamics.

Recognition and treatment of comorbidities are also a major focus of ongoing investigation in heart failure. Anemia is common in heart failure and may be caused by increased plasma volume or decreased red cell mass.[212] Contributing factors include malnutrition with iron deficiency, bone marrow suppression from activation of pro-inflammatory cytokines, and chronic kidney disease. Anemia may contribute to ventricular remodeling and disease progression by stimulating neurohormonal and cytokine activation, promoting left ventricular hypertrophy, and exacerbating ischemia. Short-term studies of erythropoietin have shown that correction of anemia improves exercise tolerance and quality of life.[213] The effects of erythropoietic agents on morbidity and mortality rates in heart failure are currently being tested in a large, controlled trial.

Like anemia, secondary pulmonary hypertension is common in patients with advanced heart failure and is associated with exercise intolerance and adverse outcomes.[214] Dysregulation of pulmonary vascular tone and structural remodeling are caused, in part, by pulmonary vascular endothelial dysfunction that results in impaired nitric oxide availability and decreased levels of cyclic guanosine-monophosphate (cGMP).[215] PDE-5 inhibitors such as sildenafil cause pulmonary vasodilation by promoting an enhanced and sustained level of cGMP. In patients with pulmonary arterial hypertension, acute administration of sildenafil decreases pulmonary vascular resistance and increases cardiac index.[216] The long-term effects of sildenafil in patients with heart failure and secondary pulmonary hypertension remain to be tested, although intermittent use of PDE-5 inhibitors appears to be safe in heart failure patients with erectile dysfunction.[190] Use of PDE-5 inhibitors is contraindicated in patients receiving organic nitrates for treatment of ischemic heart disease or heart failure.

Chapter 15

Implantable Devices for the Management of Heart Failure

William T. Abraham

CHAPTER CONTENTS

Following decades focused on pharmacologic management, the year 2001 ushered in a new era of implantable device therapies for the management of heart failure with the U.S. Food and Drug Administration (FDA) approval of the first cardiac resynchronization therapy (CRT) device. Soon thereafter, randomized controlled trials were published that supported the routine use of implantable cardioverter-defibrillators (ICDs) and of combined CRT-ICD devices in the management of heart failure (HF). Although ICDs had already been indicated for the management of resuscitated cardiac arrest, ventricular fibrillation, and hemodynamically destabilizing ventricular tachycardia in HF patients, these newer studies demonstrated mortality reduction with the prophylactic use of an ICD, substantially enlarging the population of patients eligible for an ICD. By 2005, the strength of evidence supporting the use of an ICD or CRT with or without a defibrillator in the management of HF was sufficiently strong to recommend use of these therapies in all eligible patients.[1]

In addition to the therapeutic benefits of CRT and ICDs, implantable devices that monitor HF clinical status and/or hemodynamics have been developed and are now under investigation. One such device has recently been approved by the FDA. Using measurement of intrathoracic impedance, an available CRT-ICD device can track intrathoracic fluid volume changes. Although the usefulness of this measurement is incompletely understood, preliminary findings suggest that intrathoracic impedance changes can predict episodes of worsening HF and provide an opportunity to prevent them. This strategy is now under investigation in large randomized controlled trials. Another investigational approach to managing HF is through the use of implantable hemodynamic monitoring systems. These systems enable the day-to-day management of ventricular filling pressures and other physiologic parameters, not otherwise available to the clinician. Early reports suggest a substantial opportunity to reduce HF morbidity rates (e.g., episodes of worsening HF requiring hospitalization), with the use of these devices.

This chapter reviews the use of ICDs and CRT for the management of HF, previews the promise of implantable HF monitoring devices, and mentions other investigational device therapies for HF.

IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS IN THE MANAGEMENT OF HEART FAILURE

Implantable cardioverter-defibrillators were initially applied to survivors of sudden cardiac death (SCD) to treat second episodes of ventricular tachycardia or ventricular fibrillation (see Chapter 21 for complete discussion of ICD use in secondary prevention of SCD). Patients with left ventricular dysfunction, either from ischemic or nonischemic etiologies, are at increased risk for SCD.[2,3] SCD is the leading cause of mortality in patients with HF and occurs at a rate six-to-nine times that seen in the general population. The Metoprolol CR/XL Randomized Intervention Trial in Heart Failure (MERIT-HF) showed that patients with New York Heart Association (NYHA) functional class II or III symptoms die most frequently as a result of SCD.[4] This study estimated the proportion of total mortality attributable to SCD at 64% and 59% for NYHA classes II and III patients, respectively. In contrast, the major cause of death in class IV patients in MERIT-HF was progressive or endstage HF. Thus, all but the sickest HF patients are more likely to die suddenly rather than from worsening HF.

On this background, a series of studies has expanded the use of ICDs as prophylactic therapy in at-risk subjects (see Tables 21–3 and 21–5).[5-10] These studies have focused mainly on patients with coronary artery disease (usually after myocardial infarction [MI]) and/or more recently on those with left ventricular systolic dysfunction of any cause. In the HF/left ventricular dysfunction population, the Multicenter Automatic Defibrillator Implantation Trial (MADIT) was the

first primary prevention study to show the benefit of prophylactic ICD implantation.[5] High-risk patients (N = 196) with prior MI, left ventricular ejection fraction of 35% or less, nonsustained ventricular tachycardia of 3 to 30 beats at a rate >120/minute underwent electrophysiologic testing and were randomized to an ICD versus conventional antiarrhythmic therapy (primarily amiodarone). Compared with conventional therapy, the ICD arm demonstrated an impressive reduction in all-cause mortality at 2 years (15.8% versus 38.6%, P = 0.009). However, significantly more patients in the ICD group were receiving treatment with a β-blocker, confounding the results of the trial.

MADIT was followed by a number of other encouraging studies of left ventricular systolic dysfunction patients, such as the CABG-Patch trial and the Multicenter Unsustained Tachycardia Trial (MUSTT).[6,7] However, the landmark trials establishing a role for ICDs as primary prevention of mortality in HF patients are MADIT II and the National Institutes of Health-sponsored Sudden Cardiac Death-Heart Failure Trial (SCD-HeFT).[8,10] Although underpowered to demonstrate a significant difference for its primary endpoint, the Prophylactic Defibrillator Implantation in Patients with Nonischemic Dilated Cardiomyopathy (DEFINITE) trial also contributed substantially to the burden of proof supporting prophylactic intervention with an ICD in the management of HF.[9]

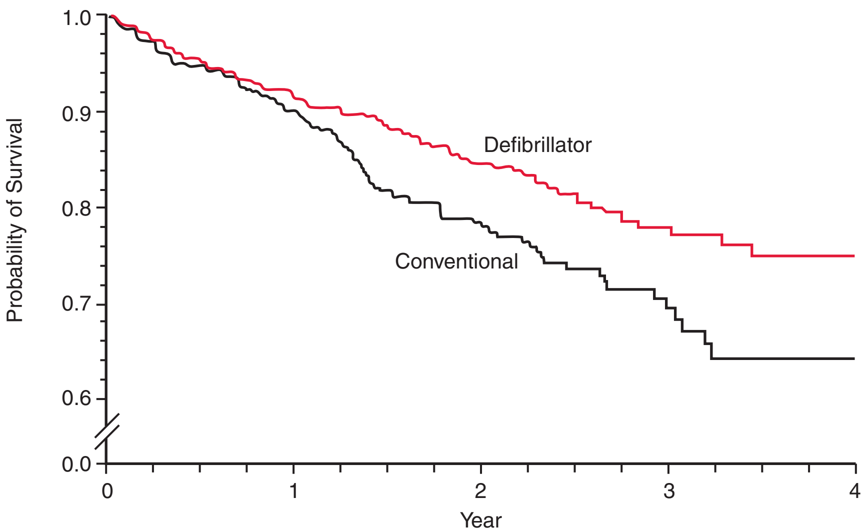
MADIT II

MADIT II, a randomized controlled trial, was prospectively designed and powered to assess the survival benefit of ICDs in a population of post-MI patients with reduced ejection fraction (<30%). Importantly, this trial included no arrhythmic markers such as nonsustained or inducible ventricular tachycardia for inclusion. A total of 1232 patients were randomly assigned in a 3:2 ratio to receive an ICD (742 patients) or conventional medical therapy (490 patients). During an average follow-up of 20 months, the all-cause mortality rates were 19.8% in the conventional therapy arm and 14.2% in the ICD group (31% relative risk reduction, P = 0.016) (Fig. 15–1). The effect of ICD therapy on survival was similar in subgroup analyses stratified according to age, gender, ejection fraction, NYHA class, and the QRS interval. Moreover, β-blocker use was 72% in these patients and was well balanced between the ICD and conventional therapy groups.

Of note, the majority of patients enrolled into MADIT II were classified in NYHA class II or III. NYHA class IV patients were excluded and the NYHA class I cohort was relatively small. The average left ventricular ejection fraction was 23%. These findings suggest that HF patients with mild-to-moderate symptoms and moderate-to-severe reduction in left ventricular ejection fraction may benefit the most from a prophylactic ICD. Moreover, in contrast to MADIT I where the survival benefit of ICD therapy was seen early post-randomization, the survival benefit observed in MADIT II began approximately 9 months after the device was implanted. The authors suggested that this difference may be due to a lower risk population being enrolled in MADIT II, the absence of arrhythmia as risk stratification for entry, and/or the use of more aggressive medical treatment. Regardless of the explanation, this observation may be important when considering the timing of device placement in eligible patients.

DEFINITE

Whereas MADIT II enrolled exclusively post-MI patients with an ischemic cause of left ventricular systolic dysfunction and HF, the DEFINITE trial was the first randomized trial of primary prevention therapy with an ICD in nonischemic cardiomyopathy patients.[9] Such patients also exhibit high rates of SCD; however, there has been little consensus regarding the management of SCD risk in such patients. This may be due, in part, to limitations in objective risk assessment, in that no invasive or noninvasive testing procedure has been shown to accurately determine which nonischemic HF patient is likely to die suddenly. Also clouding the picture were older observa-



No. at Risk

Defibrillator	742	503 (0.91)	274 (0.84)	110 (0.78)	9
Conventional	490	329 (0.90)	170 (0.78)	65 (0.69)	3

Figure 15–1 Kaplan-Meier estimates of survival in patients randomized to an ICD compared with conventional medical therapy in the MADIT II trial. P = 0.007 by log-rank test.

tions suggesting that the prophylactic administration of an antiarrhythmic agent, amiodarone, might prolong survival in nonischemic cardiomyopathy patients.[11]

The DEFINITE trial was a prospective evaluation of 458 patients with nonischemic dilated cardiomyopathy. Entry criteria included an ejection fraction of ≤35%, a history of symptomatic HF, and the presence of ambient arrhythmias defined as an episode of nonsustained ventricular tachycardia or at least ten premature ventricular contractions per 24-hour period on continuous ambulatory electrocardiographic monitoring. Patients (N = 229) were equally randomized to each arm of the study to receive either an ICD and standard medical therapy or standard medical therapy alone. Compliance with medical therapy was excellent and included an angiotensin-converting enzyme inhibitor (ACE-I) in 86% of the cohort and a β-blocker in 85%. The patients were followed for a mean of 29.0 ± 14.4 months with a primary endpoint of all-cause mortality.

There were 68 deaths reported in the DEFINITE trial, 28 in the ICD group, and 40 in the standard therapy group. The implantation of an ICD yielded a nonsignificant 35% reduction in death from any cause (hazard ratio, 0.65; 95% CI, 0.40 to 1.06; P = 0.08) and significantly reduced the risk of sudden death by a remarkable 80% (hazard ratio, 0.20; 95% CI, 0.06 to 0.71; P = 0.006). In the subgroup of NYHA class III patients, all-cause mortality was significantly decreased in the ICD arm (hazard ratio, 0.37, 95% CI 0.15 to 0.90; P = 0.02).

Although this study was underpowered and did not reach statistical significance with respect to the primary endpoint of all-cause mortality for the entire randomized cohort, the results demonstrated a strong trend toward a survival advantage for patients receiving an ICD. It is worth mentioning that the all-cause mortality reduction seen in DEFINITE was 35%, a value that is strikingly similar to the 31% relative risk reduction observed in the ischemic population studied in MADIT II. The statistical power of DEFINITE was affected by a low rate of SCD in both groups, which may be related to aggressive use of ACE-I and β-blockade in this trial.

SCD-HeFT

The results of the SCD-HeFT trial were published in 2005 and have had a substantial impact on current practice and reimbursement guidelines for ICDs.[10] This landmark randomized controlled trial enrolled 2521 patients from 148 mostly U.S. centers between 1997 and 2001. Patients with NYHA class II (70%) or III (30%) HF and reduced left ventricular ejection fraction (35% or less, mean about 25%) of either ischemic or nonischemic etiology were eligible for the study. SCD-HeFT was a three-arm trial, comparing treatment with an ICD with amiodarone and placebo. Thus, SCD-HeFT addressed at least two important issues in HF management: (1) whether or not empirical amiodarone therapy saved lives in well-treated NYHA classes II and III HF patients with no arrhythmic indication for the drug and (2) whether or not a prophylactic ICD saved lives in such patients with HF from either an ischemic or nonischemic cause.

In SCD-HeFT, patients received standard HF therapy, if tolerated, which included an ACE-I or angiotensin receptor blocker in 85%, β-blocker in 69%, and aldosterone antagonists in 19%, compatible with guidelines recommendations at the time the study was conducted. The median follow-up was 45.5 months. Importantly, the cohort was equally divided between ischemic and nonischemic causes of HF, allowing an important subgroup analysis of these cohorts to be done.

Mortality rates in the ICD, amiodarone, and placebo groups were 17.1%, 24%, and 22.3%, respectively, at 3 years and 28.9%, 34.1%, and 35.9%, respectively, at 5 years. The ICD was associated with a statistically significant 23% reduction in all-cause mortality compared with placebo (hazard ratio 0.77; 97.5% CI, 0.62 to 0.96, P = 0.007). Outcomes on amiodarone were not significantly different from placebo across all subgroups (hazard ratio 1.06; 97.5% CI, 0.86 to 1.30). Similar degrees of benefit were noted in patients with ischemic (21% mortality reduction) and nonischemic (27% mortality reduction) HF, thus confirming the findings of MADIT II and DEFINITE, respectively. The SCD-HeFT trial provides the most robust evidence to date supporting the prophylactic use of ICDs in patients with NYHA classes II and III systolic HF of virtually any cause.

INDICATIONS FOR PROPHYLACTIC CARDIOVERTER-DEFIBRILLATOR IMPLANTATION IN HEART FAILURE PATIENTS

Based on these trials, the indication for an ICD has been extended to NYHA classes II and III HF patients with a reduced ejection fraction (see Chapter 21). The 2005 ACC/AHA HF guidelines promote class I indications for the use of an ICD as primary prevention of all-cause mortality in well-treated NYHA classes II and III patients with a left ventricular ejection fraction of 30% or less and either ischemic or nonischemic cardiomyopathy.[1] There is a class IIa indication for such patients with ejection fractions of 31% to 35%. The reasoning behind these separate indications stems from the fact that MADIT II and SCD-HeFT used different ejection fraction criteria for enrollment. In any event, patients with moderate-to-severe left ventricular systolic dysfunction and NYHA class II or III HF should receive an ICD, unless there are mitigating circumstances or a contraindication to the implantation or use of this device. In this regard, the ACC/AHA guidelines qualify that ICD candidates should have a reasonable expectation of survival with a good functional status for more than 1 year, and the Centers for Medicare and Medicaid Services require waiting 3 months after surgical or percutaneous revascularization.

Practical Considerations in ICD Therapy

Before ICD implantation, patients should have a thorough understanding of the risks and benefits of device therapy, including the need for routine follow-up and defibrillation threshold testing and the morbidity associated with appropriate and inappropriate ICD shocks. Patients should understand that an ICD has been shown to prolong survival, but will not improve HF symptoms or slow disease progression. It should also be explained to the patient and family that the defibrillator function of an implantable device can be turned off as part of end-of-life care. Questions regarding exercise, driving, cellular telephones, and airport security, among others, should be anticipated and addressed in advance.

The management of complications after ICD implantation is discussed in Chapter 21. Monitoring for bleeding or infection is paramount during the early post-implant period, although seeding of the device from a distant infectious source may occur at anytime. For patients who develop new or recurrent ventricular arrhythmias that cause frequent ICD shocks, therapeutic options include antiarrhythmic drugs such as amiodarone or mexiletine, catheter ablation of ventricular tachycardia, or, in selected cases, consideration of mechanical cardiac assist or transplant. In patients with ischemic heart disease, the occurrence of polymorphic ventricular tachycardia that leads to ICD shocks should warrant reassessment for ischemia. Patients who develop significant anxiety related to ICD shocks may benefit from anxiolytic therapy and/or referral to a therapist or support group. Finally, it is important to remember that ICDs may aggravate HF as a result of mechanical dyssynchrony induced by right ventricular pacing.[12]

CONDUCTION ABNORMALITIES IN HEART FAILURE

A number of conduction abnormalities are seen in the setting of chronic HF. Approximately one third of patients with systolic HF have a QRS duration >120 msec, which is most commonly seen as a left bundle branch block (LBBB).[13,14] Such conduction delays produce suboptimal ventricular filling, a reduction in left ventricular contractility, prolonged duration of mitral regurgitation, and paradoxical septal wall motion.[15-18] These mechanical manifestations of ventricular conduction abnormalities have been referred to as ventricular dyssynchrony, especially because the septum and left ventricular free wall no longer contract in a normal near-simultaneous fashion. This situation reduces the ability of the failing heart to eject blood and has been associated with increased mortality in HF patients.[19-22]

In the mid-1990s, the application of pacing therapies to overcome ventricular dyssynchrony began to be explored. In particular, atrial-synchronized biventricular pacing—now known as cardiac resynchronization therapy or CRT—emerged as the most promising approach for the treatment of ventricular dyssynchrony. A series of studies confirmed the benefits of CRT in NYHA functional classes III and IV HF patients with ventricular dyssynchrony and led to a strong contemporary recommendation for the use of this therapy.[1]

The first application of atrial-synchronized biventricular pacing was performed by Cazeau and colleagues[23] who used four-chamber pacing in a 54-year-old man with NYHA class IV HF and significant atrial-ventricular and ventricular conduction disturbances. Standard transvenous pacing leads were placed in the right atrium and right ventricle. The left atrium was paced by a lead placed in the coronary sinus, whereas the left ventricle was paced by an epicardial lead located on the left ventricular free wall. After 6 weeks of pacing, the patient's clinical status improved markedly, with a weight loss of 17 kg and a disappearance of peripheral edema. His functional class improved remarkably to NYHA class II. Such favorable anecdotal experiences led to the inception of small studies to evaluate the acute effects of biventricular pacing on systemic hemodynamics. These studies provided additional proof of concept that CRT might reverse the deleterious consequences of ventricular dyssynchrony.[17,24] Several studies soon followed to further evaluate the acute and longer-term effects of biventricular pacing in HF.[25-33] The results were equally encouraging, with patients showing consistent, sustained improvement in exercise tolerance, quality of life, NYHA functional class, and cardiac output. With the advent of a transvenous rather than an epicardial approach for biventricular pacing, larger-scale observational and randomized controlled trials of CRT were made possible.

LANDMARK CARDIAC RESYNCHRONIZATION THERAPY CLINICAL TRIALS

Substantial evidence supports the beneficial effects of CRT for the treatment of HF. Approximately 4000 patients have been evaluated in randomized single- or double-blind controlled trials, including large-scale morbidity and mortality studies. The most important of these trials are the Multisite Stimulation in Cardiomyopathy (MUSTIC) studies,[34,35] the Multicenter InSync Randomized Clinical Evaluation (MIRACLE) trial,[36,37] MIRACLE ICD,[38] the CONTAK CD trial,[39] the Cardiac Resynchronization in Heart Failure (CARE HF) trial,[40,41] and the Comparison of Medical Therapy, Pacing and Defibrillation in Heart Failure (COMPANION) trial.[42,43]

MUSTIC

The MUSTIC trials were designed to evaluate the safety and efficacy of cardiac resynchronization in patients with advanced HF, ventricular dyssynchrony, and either normal sinus rhythm[34] or atrial fibrillation.[35] They represent the first randomized single-blind trials of CRT for HF. The first study involved 58 randomized patients with NYHA class III HF, normal sinus rhythm, and a QRS duration of at least 150 msec. All patients were implanted with a CRT device, and after a run-in period, patients were randomized in a single-blind fashion to either active pacing or to no pacing. After 12 weeks, patients were crossed over and remained in the alternate study assignment for 12 weeks. After completing this second 12-week period, the device was programmed to the patient's preferred mode of therapy. The second MUSTIC study involved fewer patients (only 37 completers) with atrial fibrillation and a slow ventricular rate (either spontaneously or from radiofrequency ablation). A VVIR biventricular pacemaker and leads for each ventricle were implanted, and the same randomization procedure just described was applied; however, biventricular VVIR pacing versus single-site right ventricular VVIR pacing (rather than no pacing) was compared in this group of patients with atrial fibrillation.

The primary endpoints for MUSTIC were exercise tolerance assessed by measurement of peak $\dot{V}O_2$ or the 6-minute hall walk test and quality of life determined using the Minnesota Living with Heart Failure questionnaire. Secondary endpoints included rehospitalizations and/or drug therapy modifications for worsening HF. Results from the normal sinus rhythm arm of MUSTIC provided strong evidence of benefit. The mean distance walked in 6 minutes was 23% greater with CRT than during the inactive pacing phase ($P < 0.001$). Significant improvement was also seen in quality of life and NYHA functional class ranking. There were fewer

hospitalizations during active resynchronization therapy. The atrial fibrillation cohort evaluated in MUSTIC demonstrated similar improvements, although the magnitude of benefit was slightly less.

MIRACLE

MIRACLE was the first prospective, randomized, double-blind, parallel-controlled clinical trial designed to evaluate the merits of CRT and to further elucidate potential mechanisms of action of CRT.[36,37] Primary endpoints were NYHA class, quality-of-life score (using the Minnesota Living with Heart Failure questionnaire), and 6-minute hall walk distance. Secondary endpoints included assessments of a composite clinical response, cardiopulmonary exercise performance, neurohormone and cytokine levels, QRS duration, cardiac structure and function (as determined by echocardiography), and a variety of measures of worsening HF and combined morbidity and mortality.

The MIRACLE trial was conducted between 1998 and 2000. Patients (N = 453) with moderate-to-severe symptoms of HF associated with a left ventricular ejection fraction ≤35% and a QRS duration of at least 130 msec were randomized (double-blind) to cardiac resynchronization (n =228) or to a control group (n = 225) for 6 months, while conventional therapy for HF was maintained.[37] Compared with the control group, patients randomized to CRT demonstrated a significant improvement in quality-of-life score (–18.0 versus –9.0 points, P = 0.001), 6-minute walk distance (+39 versus +10 meters, P = 0.005), NYHA functional class ranking (–1.0 versus 0.0 class, P < 0.001), treadmill exercise time (+81 versus +19 sec, P = 0.001), peak $\dot{V}O_2$ (+1.1 versus 0.1 mL/kg/min, P < 0.01), and left ventricular ejection fraction (+4.6% versus –0.2%, P < 0.001) (Fig. 15–2). Patients randomized to CRT demonstrated a highly significant improvement in a composite clinical HF response endpoint compared with control subjects, suggesting an overall improvement in HF clinical status. In addition, when compared with the control group, fewer patients in the CRT group required hospitalization (8% versus 15%) or intravenous medications (7% and 15%) for the treatment of worsening HF (both P < 0.05). In the resynchronization group, the 50% reduction in hospitalization was accompanied by a significant reduction in length of stay, resulting in a 77% decrease in total days hospitalized over 6 months compared with the control group. The major limitation of the therapy was caused by unsuccessful implantation of the device in 8% of patients. The results of this trial led to the FDA approval of the InSync system in August 2001, the first approved CRT system in the U.S., allowing the introduction of CRT into clinical practice.

The MIRACLE trial also provided persuasive evidence supporting the occurrence of reverse left ventricular remodeling with chronic CRT. In the MIRACLE Trial, serial Doppler echocardiograms were obtained at baseline, 3, and 6 months in a subset of 323 patients.[44] Cardiac resynchronization therapy for 6 months was associated with reduced end-diastolic and end-systolic volumes (both P < 0.001), reduced left ventricular mass (P < 0.01), increased ejection fraction (P < 0.001), reduced mitral regurgitant blood flow (P < 0.001), and improved myocardial performance index (P < 0.001) as compared with controls. These effects are similar to those seen with β-blockade in HF but were seen in MIRACLE in patients already receiving β-blocker therapy.

MIRACLE ICD

The MIRACLE ICD study was designed to be almost identical to the MIRACLE trial. MIRACLE ICD was a prospective, multicenter, randomized, double-blind, parallel-controlled clinical trial intended to assess the safety and efficacy of a combined CRT-ICD system in patients with dilated cardiomyopathy (left ventricular ejection fraction ≤35%, left ventricular end diastolic dimension ≥55 mm), NYHA class III or IV HF, ventricular dyssynchrony (QRS ≥ 130 msec), and an indication for an ICD. Primary and secondary efficacy measures were essentially the same as those that were evaluated in the MIRACLE trial, but also included measures of ICD function (including the efficacy of antitachycardia therapy with biventricular pacing).

Of 369 patients receiving devices and randomized, 182 were controls (ICD active, CRT inactive) and 187 were in the resynchronization group (ICD active, CRT active). At 6 months, patients assigned to active CRT had a greater improvement in median quality-of-life score (–17.5 versus –11.0, P = 0.02) and functional class (–1 versus 0, P = 0.007) than controls, but were no different than controls in the change in distance walked in 6 minutes (55 m versus 53 m, P = 0.36).[38] Peak oxygen consumption increased by

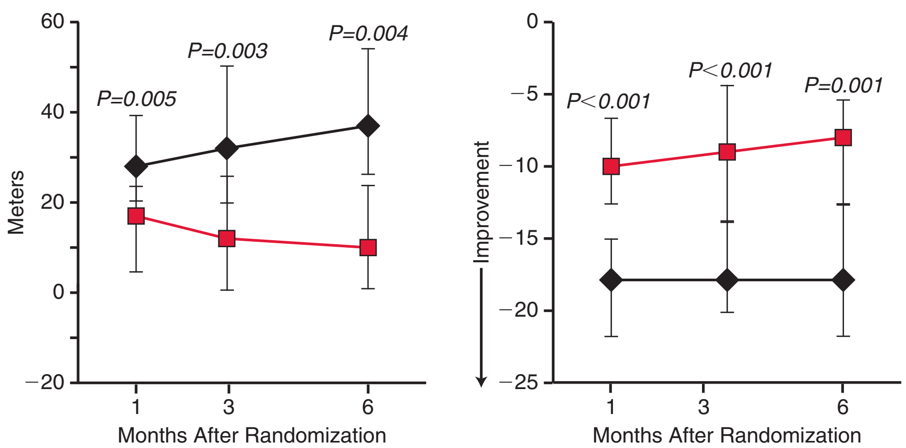


Figure 15–2 Effect of cardiac resynchronization therapy on 6-minute hall walk distance (*left panel*) and quality-of-life score (*right panel*) in the MIRACLE trial. Shown are median changes (and their respective 95% confidence intervals) at 1, 3, and 6 months after randomization in the control (*closed squares*) and the cardiac resynchronization groups (*closed diamonds*). A reduction in quality-of-life score denotes improvement. P values denote significant between-group differences. For each variable, data are shown for patients who had values at all three time points.

1.1 mL/kg/min in the resynchronization group, versus 0.1 mL/kg/min in controls ($P = 0.04$) and treadmill exercise duration increased by 56 seconds in the CRT group and decreased by 11 seconds in controls ($P = 0.0006$). The magnitude of improvement was comparable with that seen in the MIRACLE trial, suggesting that HF patients with an ICD indication benefit as much from cardiac resynchronization therapy as those patients without an indication for an ICD. The combined CRT-ICD device used in this study was approved in June 2002 by the FDA for use in NYHA classes III and IV systolic HF patients with ventricular dyssynchrony and an ICD indication.

CONTAK CD

The CONTAK CD trial enrolled 581 symptomatic HF patients with ventricular dyssynchrony and malignant ventricular tachyarrhythmias, all of whom were candidates for an ICD.[39] Following unsuccessful implant attempts and withdrawals, 490 patients were available for analysis. The study did not meet its primary endpoint of a reduction in disease progression, defined by a composite endpoint of HF hospitalization, all-cause mortality, and ventricular arrhythmia requiring defibrillator therapies, although the trends were in a direction favoring improved outcomes with CRT. However, the CONTAK CD trial did show statistically significant improvements in peak oxygen uptake and quality of life in the resynchronization group compared with control subjects, although quality of life was improved only in NYHA classes III and IV patients without right bundle branch block. Left ventricular dimensions were also reduced and left ventricular ejection fractions increased—as seen in other trials of CRT. Importantly, the improvement seen in peak oxygen consumption with cardiac resynchronization was again comparable with that observed in the MIRACLE trial. Improvements in NYHA functional class were not observed in this study. The CONTAK CD device was approved in May 2002 by the FDA for use in NYHA classes III and IV systolic HF patients with ventricular dyssynchrony and an ICD indication.

COMPANION

Begun in early 2000, COMPANION was a multicenter, prospective, randomized, controlled clinical trial designed to compare drug therapy alone with drug therapy in combination with cardiac resynchronization in patients with dilated cardiomyopathy, an IVCD, NYHA class III or IV HF, and no indication for a device.[43,44] COMPANION randomized 1520 patients into one of three treatment groups in a 1:2:2 allocation: Group 1 (308 patients) received optimal medical care only, group II (617 patients) received optimal medical care and the Guidant CONTAK TR (biventricular pulse generator), and group III (595 patients) received optimal medical care and the CONTAK CD (combined HF/bradycardia/tachycardia device). The primary endpoint of the COMPANION trial was a composite of all-cause mortality and all-cause hospitalization, measured as time to first event, beginning from time of randomization. Secondary endpoints included all-cause mortality and a variety of measures of cardiovascular morbidity. When compared with optimal medical therapy alone, the combined endpoint of mortality or HF hospitalization was reduced by 35% for patients receiving CRT and by 40% for patients receiving CRT-ICD (both $P < 0.001$). For the mortality endpoint alone, CRT patients had a 24% risk reduction ($P = 0.060$) and CRT-ICD patients experienced a risk reduction of 36% ($P < 0.003$), when compared with optimal medical therapy. COMPANION confirmed the results of earlier resynchronization therapy trials in improving symptoms, exercise tolerance, and quality of life for HF patients with ventricular dyssynchrony. In addition, COMPANION showed—for the first time—the impact of CRT-ICD in reducing all-cause mortality.

CARE-HF

The Cardiac Resynchronization-Heart Failure (CARE-HF) trial was designed to evaluate the effects of resynchronization therapy without an ICD on morbidity and mortality rates in patients with NYHA class III or IV HF and ventricular dyssynchrony.[40,41] Patients ($N = 813$) with an LV ejection fraction of 35% or less and ventricular dyssynchrony defined as a QRS duration ≥150 msec or a QRS duration between 120 msec and 150 msec with echocardiographic evidence of dyssynchrony were enrolled in this randomized, unblinded, controlled trial and followed for an average of 29 months.[41] Optimal medical therapy alone was assigned to 404 patients and 409 patients were randomized to optimal medical therapy plus resynchronization therapy. The risk of death from any cause or unplanned hospitalization for a major cardiac event, the primary endpoint analyzed as time to first event, was significantly reduced by 37% in the treatment group compared with control subjects (hazard ratio, 0.63; 95% CI, 0.51 to 0.77; $P < 0.001$). In the CRT group, 82 patients (20%) died during follow-up compared with 120 patients (30%) in the medical group, yielding a significant 36% reduction in all-cause mortality with resynchronization therapy (hazard ratio, 0.64; 95% CI, 0.48 to 0.85; $P < 0.002$; Fig. 15–3). Resynchronization therapy also significantly reduced the risk of unplanned hospitalization for a major cardiac event by 39%, all-cause mortality plus HF hospitalization by 46%, and HF hospitalization by 52%.

INDICATIONS FOR CARDIAC RESYNCHRONIZATION THERAPY IN HEART FAILURE PATIENTS

The 2005 ACC/AHA HF guidelines propose a class I indication for CRT.[1] Patients with a left ventricular ejection fraction of ≤35%, normal sinus rhythm, and NYHA functional class III or ambulatory class IV symptoms, despite recommended optimal medical therapy, and who have ventricular dyssynchrony should receive CRT, unless contraindicated. Currently, the guideline defines ventricular dyssynchrony as a QRS duration of at least 120 msec. However, echocardiography appears to be a promising way to define ventricular dyssynchrony in the future, so a newer definition of ventricular dyssynchrony may eventually prevail.

FUTURE DIRECTIONS OF CARDIAC RESYNCHRONIZATION THERAPY

There are several unresolved issues related to cardiac resynchronization therapy in HF. Despite the widespread use of CRT, further advances in device and lead technology are needed. In up to 10% of patients, percutaneous LV lead placement cannot be performed because of failure of cardiac vein cannulation. Additionally, implant procedures may be complicated by coronary sinus dissection, and late lead malfunction or dislodgment may occur. Select patients are referred for surgical epicardial LV lead placement, but outcomes are not well described. Newer lead systems and minimally invasive surgical procedures are under development and randomized studies will be needed to determine the safety and efficacy of these new techniques.

Although current guidelines recommend CRT for a broad range of patients with moderate-to-severe HF and reduced ejection fraction, there remain several HF populations in whom the benefits of CRT remain unclear. Data from the MIRACLE ICD II study showed that patients with NYHA class II HF and an indication for an ICD experienced reverse ventricular remodeling with CRT, but functional benefits were less clear.[45] The role of CRT in patients with asymptomatic LV dysfunction, as well as those with mild HF, is currently being tested in randomized controlled trials. Smaller studies also suggest a benefit of CRT in patients with atrial fibrillation or after upgrade from right ventricular to biventricular pacing, but more data are needed before strong recommendations can be made. Studies are also in progress to determine the role of CRT in patients with normal QRS duration, but with ventricular dyssynchrony documented by echocardiography. At present, CRT is not recommended for patients with unstable or refractory HF. Further investigations are needed to identify those variables that predict structural and functional responses to CRT.[46]

MONITORING HEART FAILURE THROUGH IMPLANTABLE DEVICES

Either as stand-alone devices or combined with CRT and ICD devices, implantable monitoring technologies are rapidly being applied to the management of HF. Implantable devices can provide a wealth of physiologic information about the clinical status of HF patients, and the use of this information may improve HF outcomes. For example, many implantable CRT and ICD devices can provide information on atrial heart rate and rhythm, ventricular heart rate and rhythm, patient activity level, and heart rate variability (HRV), and an increasing number of FDA-approved implantable CRT-ICD devices can also track changes in intrathoracic impedance. By monitoring trends in such parameters, it may be possible to predict episodes of worsening HF.

HF patients are encouraged to remain active and to engage in regular physical exercise, such as walking. The activity trend recorded by many implantable devices provides an objective record of the number of hours per day that patients are physically active. Thus, the activity report can serve as a useful teaching and reinforcement tool for both the patient and family about the importance and level of activity. Because exercise intolerance is a hallmark of worsening HF, a decrease in measured patient activity level may provide one clue to disease progression or decompensation. This measurement may be viewed as complementary to the patient history and, perhaps, as more objective. The predictive value of objectively measured changes in patient activity level is currently under investigation. To date, anecdotal reports suggest that a reduction in measured patient activity level precedes overt HF decompensation.

Adamson and associates[47] evaluated the usefulness of following changes in HRV as a marker of HF clinical status. HRV reflects the balance between sympathetic and parasympathetic nervous system activity in the heart, with a decrease in HRV serving as a sign of increased sympathetic and decreased parasympathetic tone.[48] This analysis showed that HRV diminished in the days to weeks leading up to a hospitalization for worsening HF, thereby suggesting that decreases in HRV can predict HF decompensation.[47] The notion that changes in continuously monitored HRV may be predictive of worsening HF is attractive because it fits well with our understanding of the mechanisms leading to worsening HF or HF disease progression—specifically activation of the sympathetic nervous system.

The ability of implantable devices to monitor fluid status is currently based on monitoring changes in intrathoracic impedance. Electrical impedance can be determined between the generator and the ICD lead residing within the right ventricle. Essentially, electrical impedance is measured across the lung, from the tip of the lead to the generator (Fig. 15–4). Because water conducts electricity better than air, increasing lung water is associated with a decrease in electrical impedance. Using this technique, electrical impedance is assessed multiple times throughout the day and then plotted on a graph. The fluid volume thresholds can be adjusted by the clinician based on patient symptoms and reviewed to determine volume status. Clinical evaluation of intrathoracic impedance changes has shown its ability to predict hospitalizations for decompensated HF 10 to 14 days in advance of the event.[49] The challenge for clinicians is knowing how to react to this information, especially in the absence of signs or symptoms of congestion. Further evaluation of intrathoracic fluid monitoring and its effects on HF outcomes is under investigation.

A new generation of even more sophisticated implantable monitoring devices is under investigation. These devices allow continuous or intermittent assessment of hemodynamics,

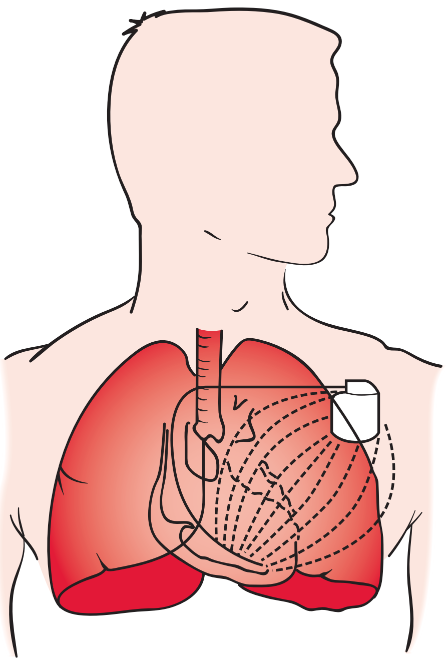

Figure 15–4 Diagram depicting the concept underlying intrathoracic impedance monitoring in heart failure. An electrical current is passed from the tip of the right ventricular lead to the "can" (i.e., generator). The impedance to the flow of electricity through the lung can be measured. Increased lung water is associated with a decrease in impedance, whereas a decrease in lung water is seen as an increase in intrathoracic impedance.

generally focused on the direct measurement or estimation of left-sided filling pressure. One of these implantable hemodynamic monitoring systems has undergone extensive evaluation in clinical trials; it has been shown to be safe, to provide an accurate estimate of left ventricular filling pressure, and to reduce the number of worsening HF events.[50-52] This system enables the continuous assessment of hemodynamics and provides this information to the clinician via a secure web site. Other systems empower patients to self-manage left ventricular filling pressure in the same way that diabetics self-manage glucose levels through the use of a glucometer. The potential for these devices to revolutionize the management of HF is substantial but remains under investigation.

FUTURE DIRECTIONS IN IMPLANTABLE DEVICES FOR THE MANAGEMENT OF HEART FAILURE

A variety of other implantable devices are under evaluation for the management of HF. In many ways, we are now in a "device era" for the management of the disease. One promising approach is cardiac contractility modulation or CCM.[53] This implantable device delivers an intermittent electrical impulse to the heart during the absolute refractory period of the ventricle. Although the mechanism of action of this investigational therapy is incompletely understood, it may be thought of as a form of electrical conditioning of the heart whereby electrically mediated changes in myocyte calcium handling improve contractility. This improvement in contractility occurs in association with a reduction in myocardial oxygen consumption, suggesting improved efficiency of the heart.[54] This favorable relationship between myocardial contractility and work has been associated with improved outcomes for other HF therapies, such as CRT. A large-scale randomized controlled trial of CCM is underway. Other implantable HF devices are in preclinical and early clinical evaluations.

SUMMARY

Cardiac resynchronization therapy offers a new therapeutic approach for treating patients with ventricular dyssynchrony and moderate-to-severe HF. Substantial experience suggests that it is safe and effective—with patients showing significant improvement in clinical symptoms and multiple measures of functional status, exercise capacity, and outcomes. The beneficial effects of CRT on ventricular structure and function have also been demonstrated in multiple clinical studies. Prophylactic implantation of an ICD is also now of proven benefit in HF patients, at least in those with NYHA classes II and III disease. Implantable monitoring technologies promise to improve our ability to avoid episodes of HF decompensation and may improve the natural history of the disease. Other investigational devices may add incremental benefit to the treatment of HF.

Chapter 16

Surgical Treatment of Heart Failure

Eric J. Velazquez

CHAPTER CONTENTS

Marked increases in the incidence and prevalence of heart failure (HF) have been observed over the last several decades.[1] This epidemiologic trend is attributed to a combination of an aging population, declining mortality associated with ischemic heart disease and hypertension (the most common causes of HF), and major therapeutic advances in the treatment of left ventricular systolic dysfunction (LVSD). Current estimates are that HF affects more than 5 million patients in the United States and is directly responsible for 1 million hospitalizations and 570,000 deaths annually with an estimated cost to society exceeding $29 billion.[2,3]

Cardiac surgical approaches to the diseased left ventricle have matured in the setting of this changing HF environment. Cardiac surgery represents one of the keystone developments in the practice of cardiovascular medicine. This chapter focuses on the current surgical approaches to the management of HF and LVSD in adults. Because they represent the most common considerations in HF patients, coronary artery bypass graft surgery, ventricular reconstruction procedures, and operative procedures to reduce mitral regurgitation are reviewed in depth as to their developmental history, current role in HF management, selection criteria, and operative considerations and outcomes. Timing of, and techniques for, surgical management of other valvular disorders, including aortic stenosis, aortic regurgitation, and tricuspid regurgitation, in the setting of HF are detailed in Chapters 46 and 47 and other reviews.[4] Some attention is given here to experimental approaches evaluated and likely to be adopted into limited clinical use. A discussion of surgically-based cellular and gene therapies for HF[5] is beyond the scope of this chapter.

Although cardiac surgery for HF has advanced greatly since the 1960s, many unanswered questions remain; these are addressed along with a brief overview of the status of ongoing clinical investigations.

CORONARY ARTERY BYPASS SURGERY

Shortly after Favaloro's description of aortocoronary saphenous vein bypass surgery,[6] initial reports followed of its application to patients with HF.[6] Although conflicting conclusions were drawn, the 30-day mortality rates of 15% and 25% in those surgical series were sobering.[7,8] Further dampening any early enthusiasm, the initial cohort studies comparing cardiac surgery with medical approaches in patients with ischemic cardiomyopathy suggested that coronary surgery led to no incremental relative improvement in either short- or longer-term symptoms or survival.[9] The high operative rates led many to consider LVSD to be a contraindication to coronary surgery and limited its initial widespread use in patients with HF.

Early efforts at medical therapy alone for ischemic cardiomyopathy probably did not alter the natural history of HF because treatment was limited to bed rest, digitalis, nitrates, and diuretics and was universally associated with poor long-term survival.[10,11] Notwithstanding the high operative mortality initially reported, the long-term mortality afforded by medical approaches alone was dismal and led to continuing efforts to expand cardiac surgery to patients with coronary artery disease, HF, and LVSD. The growing experience and continuing refinement of coronary artery bypass graft surgery (CABG) led to several case series, which suggested that surgical revascularization with or without left ventricular aneurysmectomy for patients with a left ventricular ejection fraction (EF) below 40% could be accomplished with acceptable operative mortality for that era (0% to 30%) and lead to improvements in functional status.[12-14] Furthermore, some single-center case series began reporting that surgical approaches to obstructive coronary disease with angina, HF, and LVSD could enhance 2-year survival and freedom from angina and HF compared with medical therapy.[15] Manley and colleagues also reported that, in patients presenting with angina, those treated surgically derived a long-term (6 year) survival advantage (60% versus 40%) when compared with a contemporary medically treated cohort.[16]

While operative outcomes were improving through this initial decade of coronary artery surgery, patients with severe impairments of left ventricular function remained at such high operative risk that they were excluded from the three large randomized clinical trials of coronary artery surgery or medical therapy for the treatment of chronic stable angina. Of the 2234 patients enrolled in the three landmark clinical trials between 1971 and 1979,[17-19] none had severe LVSD. Only the Coronary Artery Surgery Study (CASS) enrolled patients with any impairment of left ventricular function (EF 35% to 50%). The cohort with modest ventricular dysfunction randomized into CASS included 78 patients who underwent coronary artery surgery among whom 11 deaths occurred and 82 medically treated patients among whom 25 deaths occurred.[20] Although the survival of patients with single- and two-vessel

disease was similar among the treatments, of the 78 patients with three-vessel disease, those treated surgically instead of medically had improved survival at 7 years.

A meta-analysis by Yusuf and colleagues[22] combined individual patient data from the CASS trial with those patients enrolled in all six of the early-randomized trials of coronary surgery. Only 191 (7.2%) of the 2649 total patients enrolled had an EF less than 40%, and only 106 (4.0%) of these patients, who were primarily symptomatic with angina, also had HF symptoms. The CABG Trialists group suggested that coronary surgery led to improved survival among all patients with proximal left anterior descending artery disease, three-vessel disease, or left main coronary artery disease regardless of left ventricular function. In this analysis, a low EF increased the absolute benefit but did not change the relative benefit of coronary artery surgery. Furthermore, a 1994 literature search of 326 published reports on the results of coronary artery surgery in patients with HF or LVSD identified only three well-designed cohort studies. The mortality benefit of coronary artery surgery beyond medical therapy was estimated to be 10 to 29 lives per 100 patients treated.[23]

Patients screened for CASS with severe LVSD (EF 35% or less and poor wall motion score) not eligible for randomization were enrolled in a registry.[21] Of these 751 CASS registry patients, 231 were treated surgically and 420 were treated medically. The overall 5-year survival favored medical therapy (32% versus 46%), but only in the subset of patients (82 undergoing coronary artery surgery, 172 medically treated) with an EF less than 26% was a statistical advantage demonstrated for surgical revascularization ($P = 0.006$). In the CASS registry, the surgically treated group had more severe angina and severe coronary artery disease (66.7% with three-vessel disease and 12.6% with left main lesions >70%) in the setting of less left ventricular dysfunction and symptoms of heart failure. When the groups were evaluated by the predominance of either angina or HF symptoms, the patients with angina who were treated surgically manifested improved survival free of major functional limitation, whereas those patients with HF (11.1% surgically treated and 18.8% medically treated) did not. These data led the CASS registry investigators in 1983 to summarize their results for patients with severe LVSD by suggesting that "patients with overt heart failure and the absence of ischemic symptoms should not receive surgery." This perspective influenced treatment decisions for the next 2 decades and was cited as late as 2001 in the ACC/AHA HF Guidelines, which gave coronary revascularization for patients with HF in the absence of angina a class IIb recommendation.[24]

Since CASS there have been a multitude of single-center small case series and larger observational studies[25-31] reporting patient outcomes with coronary artery surgery in HF with LVSD. The Duke Databank experience published in 2002 is the largest of these studies and summarized the comparative results on long-term morbidity and mortality outcomes of 339 patients who received CABG and 1052 patients who were continued on medical therapy with the diagnosis of HF and an EF less than 40% and who underwent cardiac catheterization from 1969 to 1994.[32] After adjustment for differences in baseline characteristics between the groups, CABG was strongly associated with better event-free and overall survival—regardless of the extent or severity of coronary artery disease, heart failure symptoms, or LVSD. Importantly, unlike in the CASS registry, the presence of angina did not appear to discriminate patients who had a good outcome with surgery (Figs. 16–1 and 16–2).

Increasing numbers of high-risk patients, such as those with HF and LVSD, are currently referred for coronary artery surgery.[33] Fortunately, contemporary national database analyses reveal a corresponding significant decline in risk-adjusted mortality rates.[34] Technical improvements, such as the near universal use of internal mammary artery conduits, modifications to cardiopulmonary bypass and myocardial protection techniques, along with improved surgical skill and cardiac anesthesia care, have undoubtedly contributed to the greater number of high-risk patients now undergoing surgery and the better outcomes.

Topkara and colleagues analyzed 55,515 patients who underwent coronary surgery between 1997 and 1999 from the New York State database and found that LVSD was highly prevalent among patients referred for CABG, with over 35% presenting with an EF less than 40%.[35] In 14.8% of the patients, the EF was 30% or less. Patients with the lower EFs had a significantly higher in-hospital mortality rate after coronary surgery (6.5% for EF <20%, 4.1% for EF 21% to 30%, 2.7% for 31% to 40%) when compared with those patients with more preserved left ventricular function (1.4% for EF > 40%). In the lowest EF group, increasing age, female gender, hepatic insufficiency, renal failure, HF symptoms, procedural urgency, acute myocardial infarction, and previous cardiac surgery were significant predictors of a poor outcome.

Patient selection remains an important factor in achieving favorable outcomes after CABG, especially among those with HF and LVSD, and has been extensively evaluated.[36] Cardiac catheterization is mandatory to define native, and in the case of reoperation CABG, graft anatomy as well as suitability of distal vessel targets (see Chapter 8). In addition, important hemodynamic data including presence and reversibility of pulmonary hypertension and evidence of right ventricular failure assist in risk stratification and perioperative management. Careful search for end-organ dysfunction, including secondary renal and hepatic impairment, and concomitant pulmonary and peripheral arterial disease, is also necessary to assess and minimize surgical risk. One explicit goal of coronary surgery selection paradigms is to maximize the likelihood of improved functional status and survival at the lowest risk. The potential reversibility of LVSD in patients with myocardial viability has been likened by some to the holy grail of coronary surgery in HF, and it is estimated that up to 40% of patients with coronary artery disease may have the potential for improved left ventricular function after coronary surgery.[27,37]

Viability testing by various modalities is currently used by many clinicians to select appropriate patients for coronary surgery.[37-39] Positron emission tomography (PET) is considered by many to be the standard for assessing the presence and extent of hibernating myocardium.[37] Severely hypokinetic or akinetic regions that demonstrate decreased or absent perfusion in the presence of normal metabolism (assessed by ^{18}F-deoxyglucose (FDG) uptake)—also referred to as *flow-metabolism mismatch* are likely to recover function after revascularization.[40] Unfortunately, lack of availability, requirement for on-site production of isotopes, and high costs have limited the widespread use of PET imaging. An older and more readily available nuclear cardiology test is thallium-201 scintigraphy with rest and redistribution or reinjection

imaging. However, compared with PET, thallium viability testing has lower specificity, may overestimate potential improvement in EF, and is more time consuming. Given its relatively low cost and widespread availability, low-dose dobutamine stress echocardiography is the viability test of choice at many institutions. This test is based on the concept that hibernating myocardium is able to demonstrate an augmented contractile response to β-adrenergic stimulation. The addition of myocardial strain analysis may further enhance the sensitivity of this technique for viability assessment,[41] while β-receptor hypo-responsiveness and ischemia may cause false negatives. For patients without pacemakers or implantable cardioverter-defibrillators, cardiac magnetic resonance imaging is an alternative to PET for assessing viability with high sensitivity and specificity.[39] Gadolinium imaging is used to identify areas of delayed hyper-enhancement that are unlikely to recover function with surgical revascularization.

The presence of viability in patients with LVSD and coronary disease appears to predict recovery of contractile function, regardless of whether patients receive medical therapy alone or CABG.[42,43] Many retrospective, nonrandomized observational series of the association of viability testing and differential outcomes with CABG and medical therapy for ischemic cardiomyopathy have been published, with results summarized in several recent meta-analyses.[44,45] A clinical algorithm has been proposed integrating viability testing into the diagnostic and therapeutic approaches to patients with

LVSD[46] (Fig. 16–3). Although the published data, including an analysis from the Cleveland Clinic Foundation,[40] suggest that patients with coronary disease, LVSD, and viable myocardium who are eligible for revascularization may have improved short- and long-term outcomes with coronary surgery, a multitude of confounding factors limits the applicability of the data to current HF patients. In particular, additional procedures performed at the time of CABG including mitral and/or tricuspid valve repair, transmyocardial laser revascularization,[47] or placement of an epicardial left ventricular lead for cardiac resynchronization therapy[48] may significantly affect postoperative results. Nonetheless, it is unlikely that any effect of CABG over medical therapy in patients with LVSD depends solely on the presence of viability or the likelihood of functional recovery.[49]
